Abstract \(N,N'-\text{bis(4-methoxysalicyl)benzene-1,4-diamine (S1)}\) was synthesized from 4-methoxysalicylaldehyde and \(p\)-phenylenediamine and it was found to exhibit interesting aggregation-induced emission enhancement (AIEE) characteristics. In good solvent, \(\text{S1}\) displayed very weak fluorescence, whilst strong emission was observed when in poor solvent. The morphology characteristics and luminescent properties of \(\text{S1}\) were determined from the fluorescence and UV absorption spectra, SEM, fluorescence microscope and grading analysis. Analysis of the single crystal diffraction data infers that the intramolecular hydrogen bonding constitutes to a coplanar structure and orderly packing in aggregated state, which in turn hinders intramolecular C-N single bond rotation. Given that the three benzene rings formed a large plane conjugated structure, the fluorescence emission was significantly enhanced. The absolute

fluorescence quantum yield and fluorescence lifetime also showed that radiation transition was
effectively enhanced in the aggregated state. Moreover, the AIEE behavior of S1 suggests there is
potential applications in the fluorescence sensing of some volatile organic solvents.

**Introduction**

Although many organic luminescent molecules exhibit good luminescence properties in solution,
their fluorescence decreases or is quenched when aggregation occurs or in the solid state [1],
which limits the application of these molecules in thin films and the solid state. The problem of
fluorescence quenching of some organic luminescence molecules need to be solved to allow for
their efficient use in solid devices. More highly efficiency, stable and multi-colored organic
light-emitting materials need to be developed [2, 3]. A series of aggregation induced enhanced
emission (AIEE) compounds have been reported by the Tang Benzong research group [4, 5],
and more of these AIEE compounds have been found including styrene acrylic instead of nitrile [6, 7],
salicylaldehyde [8-10] and coumarin-based Schiff bases [11] etc. Our group has also reported
AIEE compounds based on phenothiazine [12] or naphthalene [13] as the structural units. AIEE
mechanisms including restriction of intermolecular rotation, formation of J-aggregates, blockage
of non-radiative relaxation pathways of the excited species, intramolecular planarization inhibition
of photoisomerization and photocyclization have been proposed [14-18]. Organic compounds,
which possess the characteristics of AIEE via changing of the molecular coplanarity, increasing
the rigid conjugate structure, conformational change and orderly accumulation under the
conditions of aggregation or in the solid state, have excellent prospects for application in organic luminous materials, chemical and biological sensors and so on.

Herein, we report 2-(1-hydroxy-2-naphthyl)methylenehydrazone (S1), which has been readily synthesized in a one step condensation reaction using 4-methoxysalicylaldehyde and \( p \)-phenylenediamine. The cyclic structure was formed by intermolecular hydrogen bonding between the Schiff base nitrogen atoms and the hydroxyl group of the benzene, which not only increases the molecular planarity, but also limits the intramolecular rotation around the single bond involving the carbon and nitrogen. Luminous efficiency can be improved through the formation of large coplanar and conjugated cyclic structures. The aggregation and the high-efficiency photoluminescence in the solid state have been investigated.

Experimental

**Materials and methods**

All chemicals used in this work, including phenylenediamine, ethanol, dimethyl sulfoxide, \( p \)-methoxy salicylaldehyde and \( \beta \)-cyclodextrin were purchased directly from chemical suppliers (Aladdin Chemical Reagent Co., Ltd., China) and were used without further purification. The cucurbit[\( n \)]urils (\( Q[n]s \ n = 5, 6, 7, 8 \)) were made in our own laboratory. All reagents were of analytical grade. Doubly-distilled water was used in all of the experiments.

Fluorescence spectra were recorded on a Cary Eclipse fluorescence spectrophotometer (Varian) equipped with a xenon discharge lamp. Absorbance spectra were recorded on a TU-1901 spectrophotometer (Beijing General Instrument Co., China). Single crystal X-ray diffraction studies were conducted on a Smart CCD Apex2 diffractometer (Bruker). Fluorescence images of the
microcrystals were obtained by a C-SHGL fluorescence microscope (Nikon) with an inverted fluorescence micro-manipulation system. Suspensions were obtained using a TGL-16GA centrifuge (Shangdong Xing Ke Intelligent Technology Co., Ltd., China). Scanning electron microscopy (SEM) images were recorded on a KYKY-2800B microscope (Beijing Branch Instrument Co., Ltd., China). The size distribution was determined by Nano ZS nanoparticle zeta potentiometer (Melvin British Co., UK). The fluorescence lifetimes and absolute fluorescence quantum yields were detected by a FLS920 steady/transient state fluorescence spectrophotometer (Edinburgh Instruments Co., UK) with an electric refrigeration photomultiplier tube detector, 375 nm excitation wavelength, with laser output pulse width 90 ps.

The synthesis of compound S1

The synthesis of compound S1 was performed according to the literature [19] and was verified by 1H NMR spectroscopy (Supporting Information, Fig. S1).

Single crystal X-ray crystallography of S1

A single crystal of S1 was grown by slow crystallization from a solution in THF and a small amount of MeOH. X-ray data were collected on a Smart ApexII CCD diffractometer, the crystal structure determination and analytical methods were the same as reported previously [20].

Preparation of S1 for SEM and fluorescence images

A 50 μM solution of S1 in DMSO/ H2O (Vol. 80% H2O) was added to a 25 mL flask, and a suspension was obtained by centrifugation. The preparation of samples for SEM involved applying a few drops of a suspension to a glass slide, which was covered with a black film. After drying at room temperature, the prepared samples were sputter-coated with gold/palladium. Samples for fluorescence microscopy were prepared by applying a few drops of a suspension to a
glass slide and then covering with a coverslip.

Results and discussion

Molecular structure

Crystallographic data for S1 have been deposited with the Cambridge Crystallographic Data Centre (CCDC-906106). Copies of the data can be obtained on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: +4401223 762911 or kamila@ccdc.cam.ac.uk].

The crystal structure of S1 belongs to the monoclinic crystal system. X-ray diffraction measurements and the experimental details for the structure analysis of S1 are given in Table 1.

AIEE property of S1

S1 can readily be dissolved in aprotic polar solvents such as DMSO, THF or DMF, but cannot be dissolved in the protic solvents MeOH, EtOH or H2O. The fluorescence spectra revealed that upon excitation of a dilute DMSO solution of S1 (10 \( \mu \)M) at 379 nm, a weak fluorescence emission was observed. However, the fluorescence intensity increased continuously when 60–80% volume fractions of H2O were added to the DMSO solution, whilst the max emission wavelength underwent a blue-shift on addition of water (Fig. 1A). When compared with the use of the DMSO solvent, there was a 5 times increase of fluorescence intensity at 510 nm when the H2O volume fraction increased up to 80% in the DMSO/ H2O mixture solvent. On the contrary, the maximum absorption at 380 nm decreased with the addition of H2O to the DMSO/ H2O mixture solvent (Fig. 1B). The AIEE phenomenon can be seen directly from the fluorescence spectral changes, and indicated the formation of aggregates in poor solvent [21].

![Fig. 1 Fluorescence (A) and UV absorption spectra (B) of S1 (10 \( \mu \)M) in a DMSO/ H2O solvent mixture. Inset: the variation of emission intensity of S1 with increasing water fraction in DMSO/ H2O mixture solvent. \( \lambda_{ex} / \lambda_{em} = 379 / 510 \) nm.]

Usually, the formation of aggregates can be observed in suspensions made by centrifugal concentration [22]. The fluorescence of S1 aggregates in DMSO/ H2O mixed solvent was
supported by observation using fluorescence microscopy. Fig. 2A shows photographs of S1 in different solvents and in the solid state at 365 nm UV illumination. No obvious fluorescence was observed in DMSO solvent [Fig. 2A (a)], but strong bright yellow-green fluorescence was observed in the DMSO/ 

H₂O (Vol. 80% H₂O) solvent mixture [Fig. 2A (b)], and a yellow-green color appeared on production of powdered S1 [Fig. 2A (c)]. Fluorescence microscopy of S1 powder also revealed strong yellow-green fluorescence (Fig. 2B), indicating aggregates of S1 in the mixed solvent and the solid-state for S1, both have the same fluorescence emission. Furthermore, the fluorescence spectra of S1 were obtained from a turbid liquid, the supernatant from centrifugation of the solution in DMSO/ H₂O, and the solid state (Fig. 2C), which validated that the measured spectra originated from the same luminophore, regardless of whether in the solid state or dispersed in solution.

The size distribution of S1 in different volume fractions of DMSO/ H₂O mixed solvent were investigated by nanoparticle zeta potentiometry (Fig. 3). When the volume fractions of DMSO were higher than 50 %, the S1 molecules tended to be distributed in the solution, and no
nanoparticles were detected; when the volume fraction of DMSO was reduced to 40%, particle size analysis revealed that there were 100–380 nm sized molecular aggregates present, i.e., the proportion increased with increasing poor solvent (H$_2$O); When the volume fractions of DMSO was reduced to 10%, the particle size of the aggregates was in the range 100–700 nm, most of which were about 200–300 nm. On decreasing of the DMSO volume fractions, the proportion of the large sized aggregates increased. This strongly suggested that the molecules of S1 existed in the form of aggregates rather than a precipitate in an appropriate ratio of a DMSO/H$_2$O solvent mix. The particle size distribution and intensity of the molecular aggregates were controlled by the proportion of poor and good solvent.

The solution of S1 in DMSO/H$_2$O (Vol. 80 % H$_2$O) mixed solvent was separated by centrifugation. An SEM image (Fig. 4A) and a fluorescence microscopy image (Fig. 4B) of the centrifuged suspension showed a nanoparticle morphology (approx. 1.44 μm) and the bright yellow-green colored nanoaggregates.

Investigation of the characteristic mechanism of AIEE

The crystal structure of S1 can help to explain the mechanism of the AIEE phenomenon by analysis of the geometrical parameters. In Fig. 5(A), the angles of C(8)-N(1)-C(10), N(1)-C(8)-C(1), C(11)-C(10)-N(1) and C(9)-C(10)-N(1) were determined as 120.92(15)°, 121.90(16)°, 123.57(15)° and 117.60(15)°, respectively; the torsion angles of C(1a)-C(8a)-N(1a)-C(10a) and C(1)-C(8)-N(1)-C(10), were determined as 176.42°, 175.67°, respectively, ie close to 180° planar angle. The dihedral angle of 0.8° proved that A and B were coplanar rings. H(1) and N(1) formed a bond length of 2.596(2) Å for the intramolecular hydrogen bonding, and this not only enlarged the conjugated plane structure of the S1 molecule from five rings, but also formed a stable six-membered ring from “-C(8)=N(1)…H(1)-O(1)-C(6)=C(1)―”, thereby ensuring intramolecular rotation was allowed only about the C-N single bond. In DMSO solvent, the S1 molecules were in the dispersion state, so for the two symmetric coplanar rings, both sides of the middle benzene ring, rotated freely around the single bond of C(10)-N(1) or C(10a)-N(1a), and it was difficult for them to adopt a coplanar rigid structure. Hence, most of the excited-state energy was lost, and the fluorescence emission was very weak. In the DMSO/H₂O
mixed solvent, aggregation of the S1 molecules occurred, and the distance between the molecules was reduced; the free rotation weakened, and therefore the co-planarity was enhanced. As shown in Fig. 5(B), the distance was only 3.8492 Å from the C(E) ring to the D(F) ring, and the molecules were able to adopt a stagger intermolecular π-π parallel stacked arrangement, which lead to rapid fluorescence enhancement; this is consistent with the literature.\textsuperscript{[23, 24]}

![Molecular structure of S1](image)

**Fig. 5** Molecular structure of S1 (A), the details of π-π interaction (B)

This AIEE effect could be explained by the blocking of the non-radiative intramolecular rotational decay of the excited molecules through the formation of aggregates \textsuperscript{[21, 25, 26]}, due to the restricted motion of S1 in the mixed solvent. The effect of S1 on the concentration was studied in different volume fractions of DMSO/H\textsubscript{2}O mixed solvent (Supporting Information, Fig. S2). When the concentration of S1 was as low as 1 nM, there was no fluorescent enhancement, even if the volume of H\textsubscript{2}O reached 40-90%, it was difficult to form aggregates at such low concentrations. Furthermore, the explanation is supported by the fluorescent enhancement of S1 as the viscosity of solvent (glycol) increased (Supporting Information, Fig. S3 and Table 1), given that high viscosity would inhibit intramolecular rotation and induce the AIEE effect. However, clear variations were
observed up to an appropriate concentration (100 μM) when the volume of H$_2$O reached 40%; the ordered stacking of aggregates is effective in limiting the intramolecular rotation. The changes of fluorescence intensity of S1 in DMSO/ H$_2$O (10 μM, Vol. 80% H$_2$O) at different temperatures were investigated (Supporting Information, Fig. S4 and Table 2), and it was found that the fluorescence intensity decreased on increasing the temperature; rotation is more facile at higher temperatures, even in the state of aggregation. At 70 °C, the fluorescence intensity of the aggregated state decreased to the same as in pure DMSO.

The luminescence properties of S1 (10 μM) versus different cavities of various macrocyclic compounds was investigated. In Fig. 6, S1 is shown to exhibit weak fluorescence emission in DMSO/ H$_2$O (Vol. 10% H$_2$O) solution due to being in the dispersed state, but exhibits high selectivity for Q[6] over other Cucurbit[n]urils (Q[n]s n = 5, 7, 8) and β-cyclodextrin (β-CD) with fluorescence enhancement, while other macrocyclic molecules (which?) did not exhibit this phenomenon. This may be attributed to complementary space matching that allows the S1 molecules to just enter into the hydrophobic cavity of Q[6], which provide a microenvironment for the luminescence molecule, thereby limiting free rotation of the intramolecular single bond, and reducing the non-radiative transition, resulting in fluorescence enhancement. This phenomenon is similar to the aggregated state in poor solvent (DMSO/ H$_2$O).

Fig. 6 Fluorescence spectra of S1 in DMSO/ H$_2$O (10 μM, Vol. 10% H$_2$O) upon the addition of
different macrocyclic molecules.

\( a. \ Q[6]; \ b. \ S1; \ c. \ Q[7]; \ d. \ Q[5]; \ e. \ Q[8]; \ f. \ CD. \ \lambda_{ex} = 379 \text{ nm.} \)

All of the above results indicate that \textit{S1} is an AIEE molecule, for which free intramolecular rotation of the fluorophore can be inhibited on going from the dispersed state to the aggregated state. The clear AIEE phenomenon of \textit{S1} was observed up to an appropriate concentration, solvent, microenvironment and temperature. The enhanced emission of the \textit{S1} solution is attributed to the combined effects of molecular planarization, ordered stacking, and inhibition of the intramolecular rotation.

The fluorescence lifetime of \textit{S1} in various organic solvents and different volume fractions of mixed solutions were determined by a steady/transient state fluorescence spectrophotometer, respectively. The transient luminescence decay curves of \textit{S1} are shown in Fig. 7. The longest fluorescence lifetime is 4.92 ns in DMSO/H\textsubscript{2}O (Vol. 80 \% H\textsubscript{2}O) solution with 1.201 goodness of fit (Table 2), and an absolute fluorescence quantum yield (\( \Phi = 0.18 \)) measured with an integrating sphere attachment. In the same solvent, the fluorescence lifetimes of \textit{S1} were enhanced on increasing the water volume fraction, due to an increase of aggregation in the poor solvent, which contributes to the orderly accumulation of molecules, and luminous efficiency enhancement. The fluorescence lifetime is slightly different in different solvents, but the variation is small. The merits of strong emission and long emission lifetimes may qualify \textit{S1} as a highly attractive candidate for organic luminescent molecules that can be used in the solid or the aggregated state.
**Fig. 7** Transient luminescence decays of S1 in the DMSO/ H2O mixture solution.

*a.* Vol. 80 % H2O; *b.* Vol. 60 % H2O; *c.* Vol. 40 % H2O.

| Table 2. Fluorescence lifetime change of S1 in different solvent system |
|-----------------------------|------------------|------------------|
| Solvent                  | DMSO/ H2O       | THF/ H2O        |
| Vol. H2O (%)             | 40   | 60   | 80   | 40   | 60   | 80   |
| τ/ns                      | 3.03 | 3.64 | 4.92 | 2.93 | 3.33 | 3.89 |

Utilization of the AIEE property of S1 as an on/off fluorescence switch in the solid/dispersed state allows it to be used as a probe for volatile organic solvent detection [27]. THF was selected as the test solvent given its strong volatility and good solvent of S1. A THF solution containing a small amount of S1 was dripped onto a thin-layer chromatography (TLC) plate, whilst observing the spot of TLC plate under 365 nm ultraviolet light at room temperature. The spot exhibited yellow-green fluorescence after evaporating off the THF solvent (Fig. 8A), and the yellow-green fluorescence spot disappeared under a vapor of THF in a petri dish which contained a small amount of THF solvent (Fig. 8B). The yellow-green fluorescence spot was observed again under ultraviolet light, and then the THF solvent of the TLC plate was evaporated (Fig. 8C), *ie* this is a reversible process. There is thus the potential of utilizing S1 as a sensor for volatile organic solvents.
Fig. 8 Photos of the spots of S1 on the TLC plates placed in the petri dish sets (A) without and (B) with THF vapor, (C) take away the solvent-vapor under 365nm UV light

Conclusions

The simple salicylaldehyde derivative S1 was synthesized readily in one step by condensation of 4-methoxy salicylaldehyde with p-phenylenediamine. The AIEE characteristics of S1 were investigated in DMSO/H2O solution by fluorescence spectroscopy. The absolute fluorescence quantum yields and the fluorescence lifetimes of S1 in different solvents revealed that it was an excellent luminescent solid and also in the aggregated state. The AIEE phenomenon may be attributed to the combined effects of intramolecular planarization, the presence of intermolecular π-π interactions and intermolecular ordered aggregation, all of which reduce the non-radiative transition in the aggregated state. Furthermore, utilizing the reversible luminescence features of S1 in the solid or dispersed state allows for the detection of volatile organic solvents.
