Abstract

Nematodes are important biological models in genetics and genomics, with research driven by basic biological as well as applied questions. The presence of holocentric chromosomes, clades with frequent polyploidy and the phenomenon of programmed DNA elimination make nematode karyotypic diversity of particular interest. Here we present a catalogue of published karyotypes of nematode species, rationalising and normalising descriptions from the previous 135 years. Karyotypes of 257 species are presented in taxonomic context. Nuclear chromosome counts range from 2 to 60. Tylenchina is identified as particularly diverse in karyotype. We highlight that Rhabditida and especially parasitic Rhabditina are well-represented, but there is a paucity of data from Enoplea, Dorylaimia, and from free-living marine groups in Chromadorea. The data have been uploaded to the Genomes on a Tree (GoAT) datasystem (<https://goat.genomehubs.org/>) for integration with ongoing, large-scale genome sequencing efforts.

Introduction

The phylum Nematoda is predicted to include over 1 million species, although only ~27,000 have been formally described¹. Nematodes are ecologically important, numerically abundant, forming the majority of individuals in many marine, freshwater and terrestrial sediments². They are also economically important as parasites impacting the health of humans, farmed animals and crop plants³. The Earth Biogenome Project⁴⁻⁶ has embarked on a major programme of sequencing to high quality the genomes of a wide range of eukaryotes as part of to understand their evolution and diversity, and this necessarily includes nematodes⁷⁻⁹. Nematode genomes are relatively compact, ranging from ~20 Mb (*Pratylenchus coffeae*, one of the smallest reported animal genomes¹⁰) to ~700 Mb (*Heligmosomoides bakeri*, a mouse gut parasite¹¹). Nematodes display a range of reproductive strategies, from asexual parthenogenesis to male-female sexual, including taxa with bet-hedging intermediate strategies¹².

One component of the process of genome assembly validation is assessment of whether the assembly estimate matches the expected karyotype. This aids materially in confirming the chromosomal pseudomolecules generated using short- and long-read data and scaffolded with single-molecule read clouds or proximity ligation sequence data derived from chromatin conformation capture methods¹³. Analysis of nematode karyotypes has been critical to biological understanding for over 100 years. Theodor Boveri described the behaviour during meiosis of the chromosomes of *Parascaris equorum*, a large intestinal nematode parasite of horses in 1887¹⁴, and his observation of chromatin diminution in this species was critical in cementing the germline-soma hypothesis¹⁵. Aggregative catalogues of genome sizes have been constructed for plants (the Kew database of plant C-values, <https://cvalues.science.kew.org/>)¹⁶ and metazoans (<https://genomesize.com>)¹⁷. The Tree of Sex project has collated karyotypic and reproductive mode information for a wide range of taxa¹⁸ and databases of chromosome counts for plants¹⁹ and animals²⁰ have been presented. Focussed analyses have analysed karyotypes of more limited groups, such as Lepidoptera²¹. Nematodes are poorly served by these databases.

Surprisingly, despite the early exploration of nematodes in cytogenetics^{14,22}, description of over 25,000 species¹, and the free-living *Caenorhabditis elegans* being adopted as a key genetic model, with a fully sequenced genome²³, a highly resolved genetic map²⁴ and a research theme focussed on chromosomal behaviour during meiosis and mitosis²⁵, nematodes are absent from the Tree of Sex database¹⁸, and poorly represented in the Animal Chromosome Counts database²⁰. This is not due to lack of data, as nematode karyotype determination has been carried out for 135 years. Collations of nematode karyotypes have been published previously (Table 1), but these suffer from being taxonomically restricted and more recently from not referring to original literature to normalise species names. Walton collated karyotypes and modes of sex determination for species of animal parasitic nematodes²⁶. Makino added to Walton's data as part of his synoptic *Atlas of the Chromosome Numbers in Animals*²⁷, including recording variant counts for

species. The Animal Chromosome Count Database (<https://cromanza94.github.io/ACC>) represents Nematoda using only the 35 species from Makino²⁰. Walton enlarged his compilation in 1959²⁸. Triantaphyllou and colleagues analysed the diverse reproductive systems of tylenchine plant parasites, and their karyotype compilations^{29,30} included both plant- and animal-parasitic species. Spakulova and colleagues³¹ reviewed published karyotypes of animal-parasitic species, adding recently-published work on Spirurina, and Sofi and colleagues³² reviewed Nematoda as part of a wider survey of parasitic Platyhelminthes, Acanthocephala and Nematoda.

Nuclear genome sequences are available for over 220 nematode species (see <https://www.ncbi.nlm.nih.gov/datasets/genome/?taxon=6231>), and several of these are resolved to chromosomal pseudomolecules. Analyses of these chromosomal assemblies has found that, despite a very high rate of within-chromosome rearrangement³³ and, contrary to expectations arising from the lack of centromeres in nematode chromosomes, movement of loci between chromosomes and fission and fusion of chromosomes is relatively rare in Rhabditida^{34,35}. In Rhabditida, chromosome-level assembly data have been used to define Nigon elements, putative ancestral linkage groups that have been stable through evolutionary time³⁵. The exceptions to this general pattern are of great interest in understanding the mechanisms that maintain stable karyotypes. In particular, genera in which chromosome numbers vary widely and ploidy changes are common offer systems where the rules of chromosome evolution can be worked out.

Here we have reviewed previous compendia of nematode karyotypes (Table 1), normalising taxonomic names, and merging disjunct animal-parasite and plant-parasite lists. We have added species for which karyotypes have been determined recently, and added karyotypes inferred from genome sequencing projects. Because of the frequent linkage between the presence of specific heterochromosomes and sex, we have, where known, included information describing the reproductive mode of the species and the karyotypes associated with sex determination. We have also noted where programmed DNA elimination has been reported. The data are openly available in the Genomes on a Tree environment (<https://goat.genomehubs.org>)³⁶, and are being used to better inform assembly and analyses of nematode genomes.

Methods

We reviewed previous compilations of nematode chromosome counts (Table 1), and normalised species names to modern concepts. We searched the literature for records poorly represented in previous compilations and reviewed recent literature to add new records. For several species, different or several chromosome numbers are reported. We reviewed these, particularly in the Meloidogyninae, and collated both modal reported number as well as variation (Table 2). We have noted reproductive modes for each species where known (Table 2). We use the term "parthenogenesis" to include all reproductive modes where female organisms are able to reproduce without the production of sperm or involvement of males. Where specific information about the mechanistic

Table 1. Core sources for nematode karyotype data.

Source	Taxonomic focus	Comments	Reference
Walton 1940	Parasitic species in Rhabditida (excluding Tylenchomorpha) and Dorylaimida, and free living Rhabditina	Reprinted as Chapter XIII, pp 191-201, in B G Chitwood and M B Chitwood (1974) "An Introduction To Nematology", University Park Press, Baltimore.	26

Schiffer 2019	Panagrolaimomorpha species	Including genome sequence report	43

basis of female-only reproduction is known, we have indicated this.

When reporting karyotypes, we have referenced the origin of the data from either a recent research paper, an original report, or one of the major compilations. For the major compilation data, we have not re-visited all sources cited. However, where compilations disagreed on chromosome number for a species, we reviewed the original literature cited. We mapped karyotypes onto a taxonomic tree of the species (Supplementary File 1) derived from NCBI TaxonomyDB. The plot in Figure 1 was produced using Interactive Tree of Life⁴⁴.

Results and discussion

We curated chromosome count data for 257 species (or isolates identified as likely species), from 95 genera, 42 families, 7 suborders and 4 orders (Table 2; Figure 1). The final species list was curated from an original list of unique names through rationalisation of records that used now-retired or synonymised names. Twenty-nine name changes were made. It may be that further, minor rationalisation is possible.

Twenty-four records were from taxa only identified to genus. These included several entomopathogenic nematode isolates (nine *Steinernema* and five *Heterorhabdites*³⁹) and several cultured, free-living parthenogenetic rhabditine⁴² and panagrolaimomorph⁴³ strains.

The species assayed had both phylogenetic and biological biases. Most records were for parasitic species, particularly animal-parasitic taxa. Most species were from order Rhabditida in class Chromadorea, including members of Rhabditina, Tylenchina and Spirurina. Very few records (nineteen) were available for taxa in Dorylaimia and none were found for Enoplia. We note that while we have attempted to represent species by the female haploid chromosome number, these data were not available in all cases. In the genus *Meloidogyne* many species are mitotic parthenogens, with karyotypes suggestive of triploidy, tetraploidy or aneuploid variations thereof. Many nominal *Meloidogyne* species appear to include demes with different chromosome numbers, and perhaps ploidies. It will be revealing to measure ploidy in *Meloidogyne* species using haploid-resolved genome sequences.

Table 2. Nematode species and their karyotypes. (a) "revised": the species name differs from that given in the original publication and was revised to match current taxonomic understanding. n.res.: not resolved to species. (b) In genus *Meloidogyne* many species are believed to be triploid or tetraploid from chromosome counts but their ploidy has not been verified. (c) Heterokaryotypic chromosomes given as [female complement]/[male complement]; 0: absence of chromosome; e.g. X-null; Empty cells indicate lack of data rather than null entries. (d) Mating systems: m/f: male/female; m/h: male/protandrous hermaphrodite; m/f/h: male/female/protandrous hermaphrodite; h: protandrous hermaphrodite; p-mi: mitotic parthenogenesis; p-me: meiotic parthenogenesis; p-ps: pseudogamous; gy: gynogenetic. Species with alternating generations are shown with a "||" separator. Empty cells indicate lack of data rather than null entries. (e) Programmed DNA elimination. Where present, the number of additional chromosomes present in somatic cells is given as "+n". If there is no increase in chromosome number this is phrased "+0". If diminution is reported but the status of karyotypic change is unknown this is phrased "-n". +X: scission of X to generate Y chromosomes and thus genetic males. Empty cells indicate lack of data rather than null entries. This table is also available at <https://tinyurl.com/NematodeKaryotypes-Table2-2023>. This link permits community commenting on the entries. We encourage submission of additional published data to be added to the resource via <https://tinyurl.com/NematodeKaryotypes>.

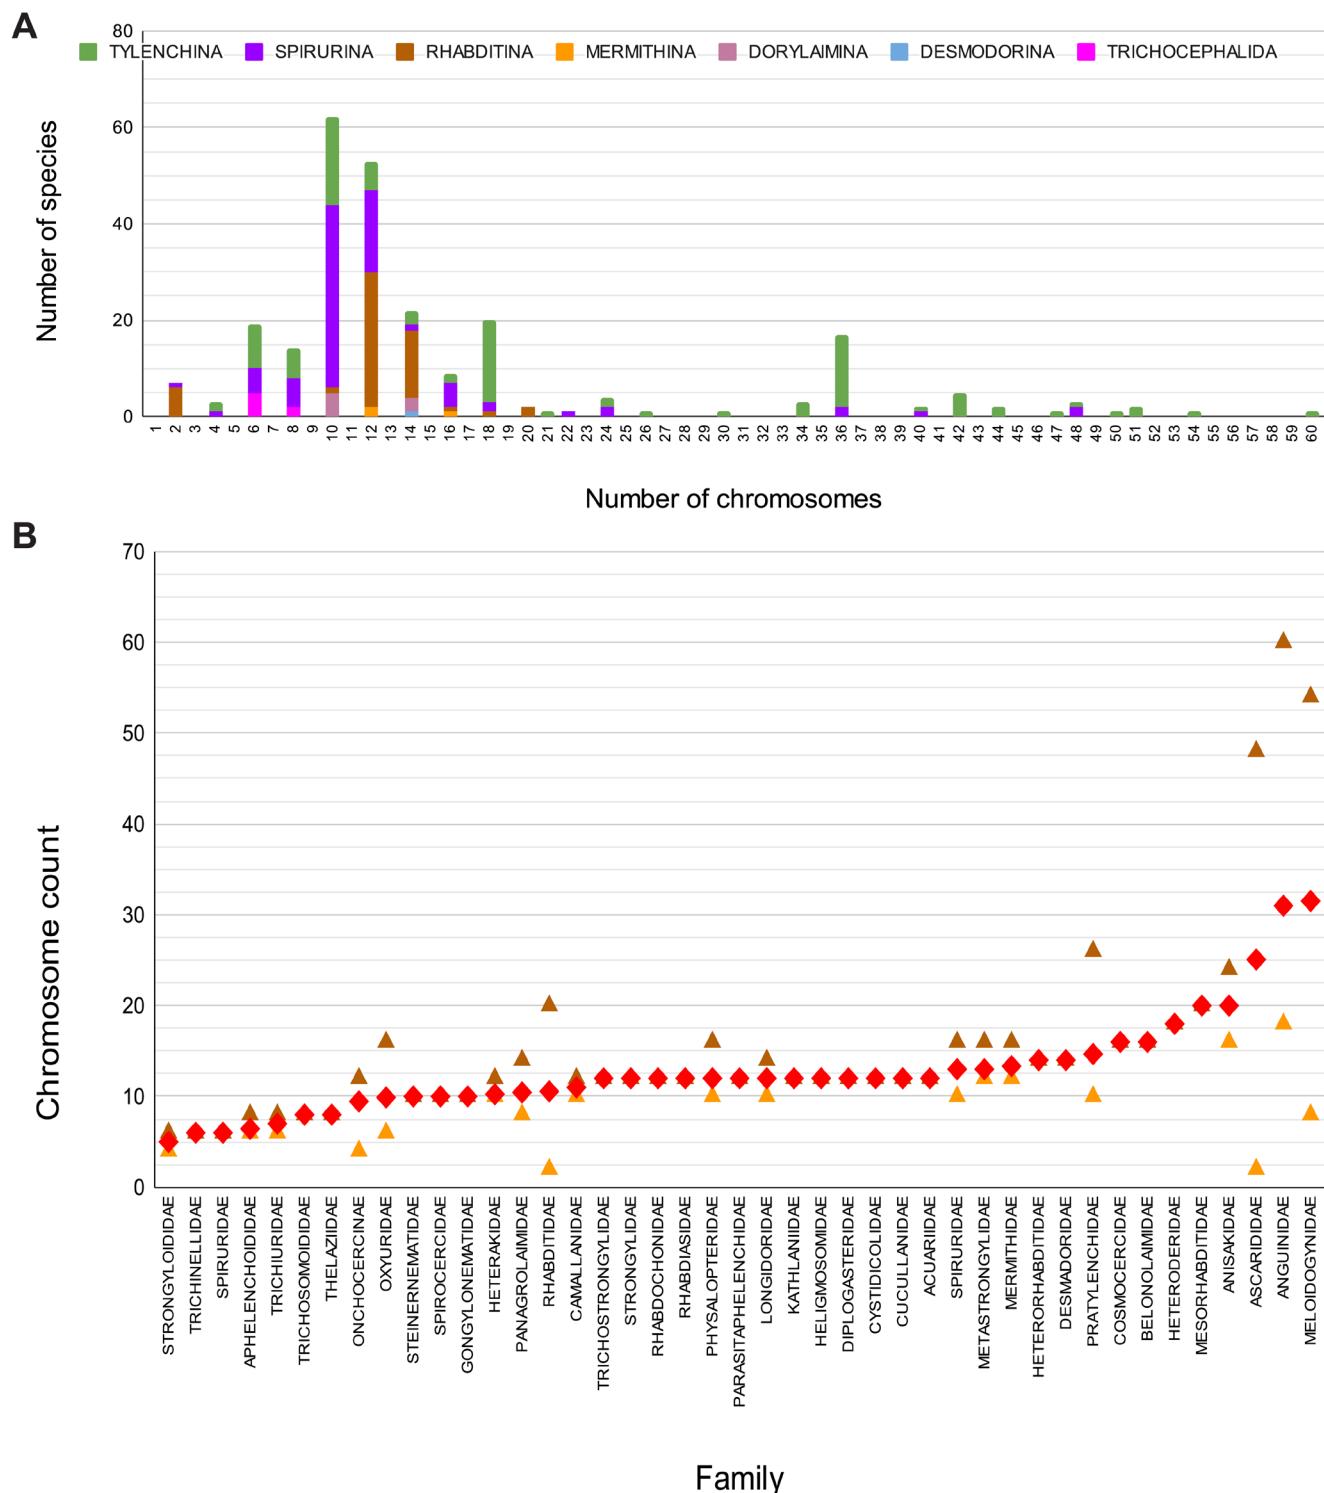

Figure 1. Chromosome numbers of Nematoda. **A** Distribution of female nuclear karyotypes, grouped by suborder. **B** Variability of female karyotype within families (ordered by average [red diamond] with lowest [orange triangle] and highest [brown triangle] count per family). The data for both panels of this figure are available at <https://tinyurl.com/NematodeKaryotypes-Table2-2023>.

In the apomictic species of *Panagrolaimus* a similar issue arises, as genomic data suggest these are AAB triploids with $3n=12$ ⁴³. Similar ploidy variability, and concomitant taxonomic uncertainty, is present in genus *Ditylenchus*¹⁰⁹.

Chromosome number variation on the phylogeny of Nematoda

Most species (81%) had inferred female haploid n of less than 10, with 54% having female chromosome counts ($2n$)

of 10, 12 or 14 (Figure 1A). In most families where data for multiple species was available, karyotypes displayed low variability (Figure 1B). Higher variability was observed in Ascarididae (Spirurina), Anguinidae (Tylenchina), Heteroderidae (Tylenchina), Meloidogynidae (Tylenchina) and Rhabditidae (Rhabditina) (Figure 1 B; Figure 2). These data may be subject to some observational bias, as in Rhabditidae, Meloidogynidae and Heteroderidae, the observation of variability of karyotype between closely related species from the same genus was a

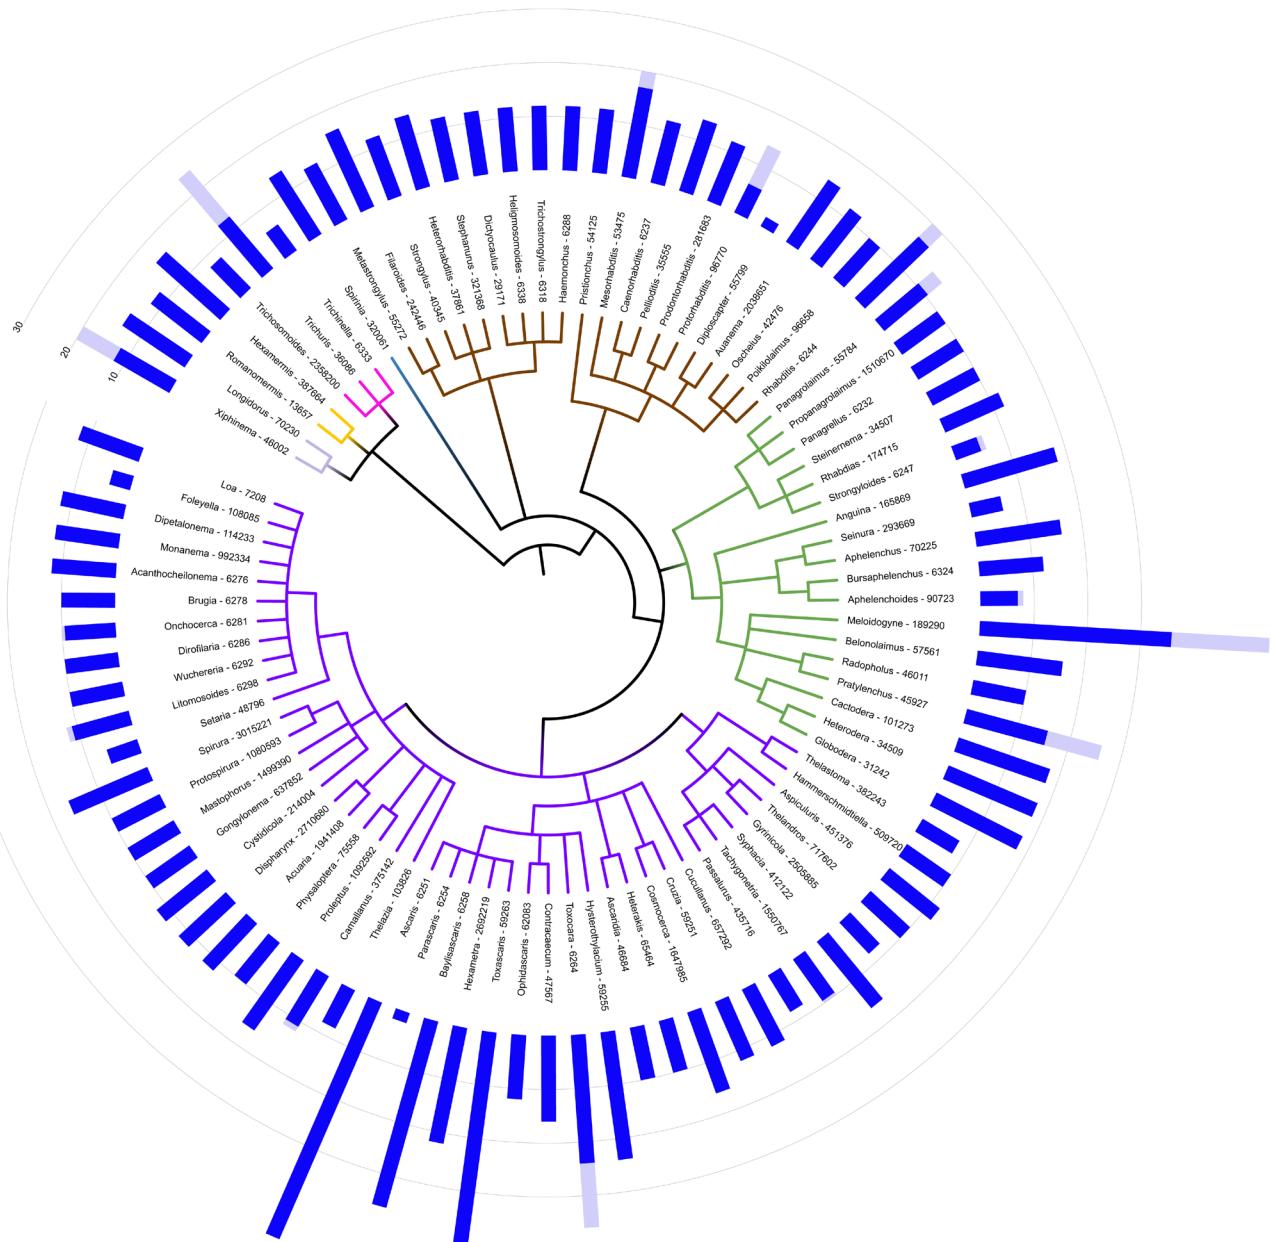

Figure 2. Phylogenetic distribution of nematode chromosome numbers. Average (dark blue) and maximum (light blue) counts of female chromosome numbers across the 90 genera (named with NCBI TXID) analysed that are present in the NCBI TaxonomyDB¹¹⁰. Five genera are not currently represented in TaxonomyDB. Clades are coloured by suborder as in Figure 1A. Note that while the NCBI TaxonomyDB recognises "Strongylida" as a distinct order, it is by molecular analysis actually nested within Rhabditina (sister to *Heterorhabditis*), and hence Rhabditina (brown) is paraphyletic in this representation. Figure developed in iTOL⁴⁴ and available at <https://itol.embl.de/export/77999098256461685686507>. An interactive version is available through <https://itol.embl.de/shared/mblaxter2>.

spur to further exploration of karyotypes of additional isolates and sister taxa. Across Nematoda chromosome numbers seem best predicted by phylogenetic neighbourhood rather than any lifestyle or reproductive mode driver.

The groups with the highest numbers of chromosomes were *Meloidogyne* species and Ascaridomorpha. In the Meloidogyninae, variation is associated with changes in ploidy between (and sometimes within) species, and also likely technical issues in counting chromosomes that are present as sub-micron dots in metaphase plates. In addition, the Meloidogyninae contain many species without meiosis, which may give them more freedom to vary in karyotype. In the ascaridids, the elevation in chromosome number is associated with the presence of programmed DNA elimination, and indeed in somatic cells of *Ascaris*, *Parascaris* and *Toxocara* species the chromosome count is increased further. The minimum chromosome number is $2n=2$, observed in *Parascaris univalens*, an ascaridid with male-female amphimixis¹¹¹, and in parthenogenetic species in the *Diploscapter-Prodontorhabditis* group, sister to *Caenorhabditis*^{42,112}.

Nigon elements and the basal karyotype

Analysis of genome sequences of Rhabditida nematodes has suggested that there were seven ancestral linkage groups in the last common ancestor of the order, termed Nigon elements A-E, N and X³⁵. In species with inferred haploid chromosome counts less than 7, the extant karyotype can be explained by simple fusion of Nigon elements in ancestral species, even if the genes that define Nigon elements are intermixed in current chromosomes. The Nigon elements each present as distinct chromosomes in at least one species³⁵. Nigon elements were defined based on genomic sequence from species in Rhabditida and it remains unclear as to whether the Nigon model extends to other Chromadorea, and to Dorylaimea and Enoplea. The limited data available for Dorylaimea suggests similar low chromosome count in trichocephalid and mermithid species, but the relationship of these chromosomes to the rhabditid Nigon elements is not clear.

Within-species variation in karyotype

For several species multiple different chromosome counts have been reported (Table 2). Some of these variant counts may be due to the technical difficulties of counting very small chromosomes in microscope preparations, but true biological variation within species is also likely. Other variant counts may arise from the systematic complexity of the taxa. Chief among these is the phytoparasitic genus *Ditylenchus*, where host-specific isolates, many of which differ in sexual mode, ploidy and observed karyotype^{60,61}, have been classified as either members of highly variable species or as distinct taxa¹¹³ and where the monophyly of the genus is questionable¹¹⁴. We have followed recent molecular species concept analyses of this genus^{113,114} and report both the common diploid karyotype for *Ditylenchus dipsaci* ($2n=24$) as well as variant counts for the *D. dipsaci* species complex^{109,115}, and counts for *Ditylenchus gigas*⁶². Another group where high variability within a species has been found is the genus *Meloidogyne*.

The variability of counts here is noted by the original authors to be in part due to technical difficulties in assessment¹¹⁶, but real differences within species are present³⁸. Again, some of these differences are likely to be due to differences in ploidy between isolates, and many species have triploid, tetraploid or sub-polyploid karyotypes^{38,117,118}.

A second source of variation between individuals within species derives from chromosomal mechanisms of sex determination, where males and females differ in chromosome complement. Sex determination in most sexual nematode species is reported as being through X-to-autosome ratio assessment, where XX animals are female and X-null (X0) animals are male. In all cases where a genomic sequence is available for analysis, the conserved loci that define NigonX are found on the biological X chromosome, suggesting that the NigonX element has ancestral sex determination roles in Rhabditida³⁵. In several ascaridid species there are multiple X chromosomes, with eight in *Toxocara canis* (where females are X8X8, and males X8-null). The few descriptions of nematode XX:XY chromosome systems, where males carry a male-specific Y chromosome, are sporadic on the phylogeny, and suggest *de novo* evolution of Y chromosomes⁴¹. In Oxyuridomorpha Adamson has identified haplo-diploidy as a sex determination mechanism⁴⁰. In some taxa, such as Mermithidae¹¹⁹, sex determination is environmental.

Strongyloides and relatives display a fascinating alternation of reproductive mode, where an amphimictic, free-living generation can give rise to mitotic parthenogenetic females, which are gut parasites in mammals¹²⁰. Males are generated by elimination of an X chromosome during maturation of the diploid oocyte. In *Strongyloides papillosus* (Panagrolaimomorpha), males are generated in the mitotic parthenogenetic parasitic female germlines through loss of a segment of a presumed X chromosome¹²¹.

An additional source of within-species variation in karyotype is the presence of supernumerary or B chromosomes. B chromosomes have been described in some populations of *Trichuris ovis* and *Trichuris globulosa* in Trichocephalida and *Onchocerca volvulus* and *Onchocerca gibsoni* in Spirurina¹²². Interestingly, these very small elements have only been observed in species with proposed XX:XY sex determination systems, and these B chromosomes may be relict, degenerating fragments of the second copy of the X-fused autosome.

Germline karyotypes and somatic karyotypes

It is notable that in species in Ascarididae, where female chromosome counts range from 2 to 48, a difference between germline and somatic chromosome numbers is observed due to the process of programmed genome elimination¹²³. For example, in female *Ascaris suum* the germline has $2n=48$ and the soma has $2n=72$. This change is the result of breakage of seven autosomes and three of the five X chromosomes at specific points, with addition of new telomeres and loss of internal sequence. The chromosomes are also trimmed at the germline telomeres¹¹¹. This process of chromatin diminution

associated with increased chromosome number in somatic cells has also been described in the ascaridids *Parascaris equorum* and *Toxocara canis*. In the rhabditine species *Oscheius tipulae*, chromatin diminution results in the loss of material from the germline chromosomes with no change in somatic karyotype³⁵, while in *Mesorhabditis belari* diminution also changes the somatic karyotype¹²⁴. While it is evident that some species do not undergo diminution, the observation that *Oscheius tipulae* loses only 0.5% of its DNA through elimination means that it is possible that additional species do. If diminution is common across the phylum it may contribute to some reported within-species variability if different authors assessed germline *versus* somatic tissues. We note that programmed DNA elimination may have predisposed ascaridid species to chromosomal breakage, and thus elevated chromosome counts, but we note that a similar process in *Oscheius* species is not accompanied by changes in germline chromosome count.

Conclusions

The phylum Nematoda is a rich ground in which to explore the pattern and process of chromosome complement evolution and the impacts of reproductive mode on karyotype and chromosome change. Genomic analyses now ongoing will increase the number of species with karyotypes determined from genome assemblies, especially where chromatin conformation capture or Hi-C data are used to generate chromosomally-complete genome sequences⁶⁷. Most genome sequences available to date have been determined from large parasitic species which can be collected in bulk from wild hosts or laboratory-maintained host-parasite systems or from free living species in *in vitro* culture. In the future, application of

sequencing methods that require very low DNA input, to the level of a single specimen with ~1000 cells, may broaden the diversity of nematodes accessible to genomics and karyotyping-by-sequencing. This will be particularly important in generating karyotypes from neglected free-living marine, freshwater and terrestrial groups.

The data described herein has been incorporated into Genomes on a Tree (GoAT)³⁶, an open datasystem that collates genomic and karyotypic data across Eukaryota. This integration supports the coordination and delivery of goals of the Earth BioGenome Project – to sequence all life for the future of life¹²⁵. GoAT presents karyotypic and genome size data in a taxonomic framework, using measures made in named species to infer the likely values for species where no direct measurements are available. Although an earlier (2021) version of the dataset was incorporated into GoAT, the current catalogue of karyotypes of Nematoda is the first full release of the dataset. It can be accessed through GoAT, for example as a histogram plot of nuclear chromosome count. We invite the addition of new karyotypic data or the inclusion of older work not yet captured by us or others, at <https://tinyurl.com/NemaKaryotypes>.
