## Abstract

This paper compiles the technical characteristics and operating principles of the Nortek Vectrino Profiler and reviews previously reported user experiences. A series of experiments are then presented that investigate instrument behaviour and performance, with a particular focus on variations within the profile. First, controlled tests investigate the sensitivity of acoustic amplitude (and Signal-to-Noise Ratio, SNR) and pulse-to-pulse correlation coefficient,  $R^2$ , to seeding concentration and cell geometry. Second, a novel methodology that systematically shifts profiling cells through a single absolute vertical position investigates the sensitivity of mean velocities, SNR and noise to: (a) emitted sound intensity and the presence (or absence) of acoustic seeding; and (b) varying flow rates under ideal acoustic seeding conditions. A new solution is derived to quantify the noise affecting the two perpendicular tristatic systems of the Vectrino Profiler and its contribution to components of the Reynolds stress tensor. Results suggest that for the Vectrino Profiler:

1. optimum acoustic seeding concentrations are ~3,000 to 6,000 mg L<sup>-1</sup>;
2. mean velocity magnitudes are biased by variable amounts in proximal cells but are consistently underestimated in distal cells;
3. noise varies parabolically with a minimum around the “sweet spot”, 50 mm below the transceiver;

4. the receiver beams only intersect at the sweet spot and diverge nearer to and further from the transceiver. This divergence significantly reduces the size of the sampled area away from the sweet spot, reducing data quality;
5. the most reliable velocity data will normally be collected in the region between approximately 43 and 61 mm below the transceiver.

**Key words:** acoustic Doppler velocimetry, Vectrino Profiler, noise, bias, sensitivity

## 1 Introduction

Acoustic Doppler Velocimeters (ADV) are a popular class of instrument for measuring the velocity of water. The popularity of ADVs can be attributed to their relatively low cost, portability and robustness, together with the capability to measure instantaneous at-a-point three-component velocities at sampling rates sufficient to capture turbulent flow processes in laboratory and field environments (e.g. Kraus *et al* 1994, Lohrmann *et al* 1995, Voulgaris and Trowbridge 1998, McLelland and Nicholas 2000, Garcia *et al* 2005, Chanson *et al* 2008). Recently, profiling ADVs have been developed, permitting the concurrent measurement of velocities at a number of different points (i.e. over a profile) (Lhermitte and Lemmin 1994, Lemmin and Rolland 1997, Hurther and Lemmin 1998, Zedel and Hay 2002, Craig *et al* 2011). Profiling ADVs have the obvious advantage of permitting more rapid data collection and the computation of instantaneous velocity gradients (Lhermitte and Lemmin 1994). To date, the only commercially-available profiling ADV is the Nortek Vectrino Profiler, launched in 2010.

Although the Vectrino Profiler has proved to be very popular in the scientific community, some scientists have already critiqued the quality of measurements performed with it. In work that was supported by Nortek through the provision of a Vectrino Profiler, Zedel and Hay (2011) found that neighbouring profiles of Reynolds shear stress did not overlap and that profiles of normal stresses exhibited structure that was not observed in measurements using a non-profiling ADV nor with Laser Doppler Velocimetry. In addition, they unexpectedly found non-zero mean lateral velocities, which also did not overlap between neighbouring profiles. Zedel and Hay (2011) suggested that calibration problems were the cause of these unexpected observations. Ursic *et al* (2012) towed a Vectrino Profiler at four different velocities (0.238, 0.476, 0.713 and 0.951 m s<sup>-1</sup>) and at four different orientations (0, 90, 180 and 270° to the tow direction) within a 30.48 m long × 1.22 m wide × 0.61 m deep flume. They reported that the vertical extent of acceptable turbulence statistics may reduce as mean velocity

1  
2  
3 63 is increased, possibly due to probe head wake effects. In comparison to a non-profiling ADV,  
4 64 they also reported increased sensitivity of results to destructive interference associated with  
5 65 acoustic reflections from the bed. MacVicar *et al* (2014) critically assessed the Vectrino  
6 66 Profiler, focussing on apparent errors in profiles of standard deviation: the standard deviation  
7 67 was minimal in the “sweet spot” and increased when moving away from the sweet spot. The  
8 68 Signal-to-Noise Ratio (SNR) was found to affect both the mean velocity and the standard  
9 69 deviation of the measured velocity time series. In addition, MacVicar *et al* (2014: 1955) noted  
10 70 that successive profiles of mean velocity were “slightly discontinuous, but broadly consistent”.  
11 71 The findings of Ursic *et al* (2012) and MacVicar *et al* (2014) were recently echoed by Leng  
12 72 and Chanson (2017) for both steady and unsteady flows. Furthermore, the knowledge center  
13 73 section of Nortek’s website ([http://www.nortek-as.com/en/knowledge-](http://www.nortek-as.com/en/knowledge-center/forum/vectrinoii)  
14 74 [center/forum/vectrinoii](http://www.nortek-as.com/en/knowledge-center/forum/vectrinoii)) is replete with users who have observed that individual profiles of  
15 75 mean velocities, variances and thence turbulent kinetic energy exhibit unexpected forms and  
16 76 that neighbouring profiles do not overlap. Brand *et al* (2016) observed a parabolic noise profile  
17 77 that contaminates the variances. They attributed this to Doppler noise and showed that the noise  
18 78 affecting the two orthogonal systems of receivers is not equal. Consequently, the assumptions  
19 79 of the noise correction method of Hurther and Lemmin (2001) are not valid for the Vectrino  
20 80 Profiler.

30  
31  
32  
33  
34 81 Given the preceding discussion, this paper makes five contributions to the literature.  
35 82 First, it details the technical characteristics and operation of the Vectrino Profiler, including  
36 83 phase Doppler theory, the physical behaviour that yields phase shifts, the pulse-pair algorithm,  
37 84 ping interval and ping interval algorithm selection, the technical implementation of profiling  
38 85 within the Vectrino Profiler and the transformation of on-axis beam velocities to Cartesian  
39 86 velocities using the calibration matrix that is unique to each cell and each probe. Second, it  
40 87 explores the sensitivity of acoustic amplitude returns (and Signal-to-Noise Ratio, SNR) and  
41 88 pulse-to-pulse correlation coefficient,  $R^2$ , to seeding concentration, cell size and cell position  
42 89 relative to the transceiver. Third, it derives a new solution for quantifying the noise affecting  
43 90 the two perpendicular tristatic systems of the Vectrino Profiler and then quantifies the  
44 91 contribution of noise to the second order flow statistics (variances and covariances). Fourth, it  
45 92 quantifies the sensitivity of mean velocities, SNR and noise to emitted sound intensity (referred  
46 93 to as power level in Nortek’s MIDAS software), acoustic seeding and flow rate. Finally, it  
47 94 describes and explores the cause of apparent bias in mean velocities and second order flow  
48 95 statistics. In making these contributions, this paper provides critical reflections on the  
49 96 operational principles of the Vectrino Profiler and the quality of data collected with it.

## 97 2 Vectrino Profiler: Technical characteristics and operation

98 The Vectrino Profiler uses similar mechanical components to the Nortek Vectrino ADV  
 99 (pressure housing, acoustic transducers and probe), but it uses completely new software (Multi-  
 100 Instrument Data Acquisition System; MIDAS), electronics and firmware (Craig *et al* 2011).  
 101 Like the Vectrino, the Vectrino Profiler consists of a single central transceiver in conjunction  
 102 with four passive receivers angled at 30° towards the transceiver. The geometrical arrangement  
 103 of these components produces a focused intersection point approximately 50 mm below the  
 104 transceiver (this point is known as the “sweet spot”). The transceiver emits paired acoustic  
 105 pulses  $\Delta t$  (called the ping interval) apart that are reflected by *in situ* scattering particles or  
 106 microbubbles in the water and then detected by two or more receivers (figure 1(a)). The  
 107 velocity of any scatterers is estimated using the measured phase shift  $\Delta\phi$  between the  
 108 transmitted and received signals. Thus, a key assumption is that any acoustic scatterers are  
 109 transported at the same velocity as the host fluid and that the velocity of the scatterers is a good  
 110 approximation of the velocity of the host fluid. All these characteristics are the same as those  
 111 of the Vectrino. However, in contrast to SonTek’s LabADV and MicroADV and Nortek’s NDV  
 112 (e.g., Kraus *et al* 1994, Lohrmann *et al* 1995, SonTek 1997, 2001, Voulgaris and Trowbridge  
 113 1998, McLelland and Nicholas 2000), the receivers of the Vectrino Profiler work  
 114 simultaneously, rather than sequentially, enabling a significant increase in the velocity  
 115 sampling rate. In addition, unlike the LabADV, MicroADV and NDV, a dwell time between  
 116 pulses is only necessary when using transmit pulses longer than 1 mm combined with  $\Delta t < 175$   
 117  $\mu\text{s}$  and is employed to avoid overheating of the acoustic transceiver. Of course, the key  
 118 difference between the Vectrino Profiler and its predecessors is the ability to quasi-  
 119 simultaneously sample three-component velocities at multiple locations beneath the  
 120 transceiver, i.e. to collect quasi-instantaneous velocity profiles.

### 121 2.1 The pulse pair algorithm for determining the phase shift

122 The phase shift  $\Delta\phi$  is calculated using the established pulse pair processing algorithm (Miller  
 123 and Rochwarger 1972, Zrnica 1977, Lhermitte and Serafin 1984). If the complex-valued sample  
 124 of pulse 1 is denoted as  $z_1$  and the complex-valued sample of pulse 2 is denoted as  $z_2$ , the  
 125 argument of their covariance is an estimate of the phase shift  $\Delta\phi$  between the two pulses:

$$127 \Delta\phi = \arg(z_1 \cdot z_2^*) = \tan^{-1} \left[ \frac{\text{Re}(z_2)\text{Im}(z_1) - \text{Re}(z_1)\text{Im}(z_2)}{\text{Re}(z_1)\text{Re}(z_2) + \text{Im}(z_1)\text{Im}(z_2)} \right] \quad (1)$$

128

129 where the asterisk denotes the complex conjugate. However, the noise associated with this  
 130 estimate is substantial and must be reduced by averaging multiple pulse pairs. Denoting the  
 131 actual number of pulse pairs as  $NPP$  and the pairs themselves as  $(z_{p,1}, z_{p,2})$ , with  $NPP \geq p \geq 1$ ,  
 132 the best estimate of the phase difference is given by (Miller and Rochwarger 1972, Zrnic 1977,  
 133 Lhermitte and Serafin 1984):

134

$$135 \Delta\phi = \arg\left(\frac{1}{NPP} \sum_{p=1}^{NPP} z_{p,1} \cdot z_{p,2}^*\right) = \tan^{-1} \left[ \frac{\sum_{p=1}^{NPP} \text{Re}(z_{p,2})\text{Im}(z_{p,1}) - \text{Re}(z_{p,1})\text{Im}(z_{p,2})}{\sum_{p=1}^{NPP} \text{Re}(z_{p,1})\text{Re}(z_{p,2}) + \text{Im}(z_{p,1})\text{Im}(z_{p,2})} \right] \quad (2)$$

136

137 Additionally, when multiple pairs are averaged, it is possible to define a complex-valued  
 138 correlation coefficient  $R^2$  by normalizing the correlation of the signals with their energy (Zedel  
 139 *et al* 1996, Zedel 2008):

140

$$141 R^2 = \frac{\sum_{p=1}^{NPP} z_{p,1} \cdot z_{p,2}^*}{\sum_{p=1}^{NPP} |z_{p,1}| \cdot |z_{p,2}|} \quad (3)$$

142

143 Note that the phase shift  $\Delta\phi$  can be calculated directly from  $R^2$ , since  $\Delta\phi = \arg(R^2)$ . The  
 144 modulus operators in the denominator are approximated using the ‘‘alpha-max plus beta-min’’  
 145 algorithm, which introduces a periodicity of  $\pi/4$  rad with maxima at  $\pm k\pi/4$  rad ( $k$  even), minima  
 146 at  $\pm l\pi/8$  rad ( $l$  odd) and a potential error of up to  $\sim 4\%$  in  $R^2$ -values, but this should have no  
 147 influence on velocity estimates (R. Craig, personal communication, 4 September, 2012).  
 148 Following Zedel (2008), equation (3) can be rewritten as:

149

$$150 R^2 = \frac{\sum_{p=1}^{NPP} z_{p,1} \cdot (z_{p,1} e^{-i\Delta\phi} + N e^{-i\gamma})}{\sum_{p=1}^{NPP} |z_{p,1}| \cdot |z_{p,1} e^{-i\Delta\phi} + N e^{-i\gamma}|} \quad (4)$$

151

152 where  $z_{p,2}$  has been expressed as  $z_{p,1} e^{-i\Delta\phi} + N e^{-i\gamma}$  to explicitly show that  $z_{p,2}$  comprises a  
 153 term due to the phase-shifted emitted pulse,  $z_{p,1} e^{-i\Delta\phi}$ , and a term due to incoherent backscatter  
 154 (noise) caused by random fluid motions and changes in backscatter strength,  $N e^{-i\gamma}$ , where  $N$   
 155 is the amplitude of the incoherent backscatter and  $\gamma$  is a random angle. The magnitude of  $R^2$  is  
 156 therefore a measure of the energy in coherent backscatter relative to the total backscatter energy  
 157 (Zedel 2008) or of the consistency of the phase shift of each sample, and can be used to assess  
 158 data quality. If  $N$  is small,  $R^2 \rightarrow 1$  and estimates of  $\Delta\phi$  are reliable. Conversely, if  $N$  is large,

1  
2  
3 159  $R^2$  decreases and estimates of  $\Delta\phi$  are less reliable since the phase difference between  $z_{p,1}$  and  $N$   
4  
5 160 is random (Zedel 2008). Low  $R^2$ -values indicate unreliable estimates of phase because they  
6  
7 161 signify the violation of assumptions about the width and shape of the signal spectral density  
8  
9 162 function used to estimate the phase of the received signal (Lhermitte and Serafin 1984). For  
10  
11 163 non-profiling ADVs, the acceptable lower bound for  $R^2$  is 70% (Nortek 1997), but it is unclear  
12  
13 164 whether this bound applies to the Vectrino Profiler.

## 15 165 2.2 Calculating fluid velocity from phase shift

16 166 For the case of a single pulse-pair and a bistatic system with one transceiver and one receiver  
17  
18 167 depicted in figure 1(b), the time rate of change of the distances between a scatterer and the  
19  
20 168 transceiver,  $\Delta R_T$ , and a scatterer and a receiver,  $\Delta R_R$ , are (Zedel 2008, Kalantari *et al* 2009):  
21  
22

23 169  
24  
25 170 
$$\frac{\Delta R_T}{\Delta t} = V \cos(\delta + \beta/2) \quad (5)$$

26  
27 171 
$$\frac{\Delta R_R}{\Delta t} = V \cos(\delta - \beta/2) \quad (6)$$

28  
29 172  
30  
31 173 where the velocity,  $V$ , makes a random angle  $\delta$  with the bisector of the angle  $\beta$  between the  
32  
33 174 paths of the transmitted and received pulses. The time rate of change of total travel distance of  
34  
35 175 a pulse ( $\Delta R = \Delta R_T + \Delta R_R$ ) is thus:

36 176  
37  
38 177 
$$\frac{\Delta R}{\Delta t} = V \left[ \cos\left(\delta + \frac{\beta}{2}\right) + \cos\left(\delta - \frac{\beta}{2}\right) \right] = 2V \cos(\delta) \cos\left(\frac{\beta}{2}\right) = 2V_b \cos\left(\frac{\beta}{2}\right) \quad (7)$$

39  
40 178  
41  
42 179 where the velocity  $V_b = V \cos(\delta)$  is introduced, denoting the velocity projected onto the  
43  
44 180 bisector (figure 1(b)). This velocity is called the beam velocity, and is the rawest velocity  
45  
46 181 estimate that the user can obtain from the Vectrino Profiler.

47 182  
48  
49 183 Next, the phase shift  $\Delta\phi$  between the two pulses is expressed as:

50  
51 184  
52  
53 185 
$$\Delta\phi = \frac{2\pi f}{c} \Delta R = \frac{2\pi f}{c} 2V_b \cos\left(\frac{\beta}{2}\right) \Delta t \quad (8)$$

54  
55 186  
56  
57 187 where  $f$  is the frequency of sound emitted by the transceiver (10 MHz in the case of the Vectrino  
58  
59  
60

188 Profiler), and  $c$  is the speed of sound within the fluid ( $\approx 1480 \text{ m s}^{-1}$ , dependent on temperature  
 189 and salinity). Rearranging,  $V_b$  can be written as a function of the measured phase shift:

$$191 \quad V_b = \frac{c}{4\pi f} \frac{1}{\cos(\frac{\beta}{2})} \frac{\Delta\phi}{\Delta t} \quad (9)$$

192  
 193 Note that the effect of the Doppler shift on the frequency is neglected, which is a good  
 194 approximation given the magnitude of the speed of sound compared to the measured velocity.  
 195 Although equation (9) was derived for a single pulse-pair, the same equation is adopted when  
 196 multiple pulse-pairs are averaged to determine a more robust estimate of  $\Delta\phi$ .

### 197 **2.3 Velocity ambiguity and the dual pulse-pair repetition scheme**

198 The phase angle from which the velocity is determined can only be resolved within the range  
 199  $-\pi$  to  $+\pi$  due to the periodicity of the arctangent function in equation (2); if  $\Delta\phi$  falls outside this  
 200 range, phase wrapping or aliasing will occur (Franca and Lemmin 2006). This is termed the  
 201 ambiguity problem on the phase shift and is associated with a similar ambiguity on the velocity.  
 202 By substituting the maximum phase shift ( $\Delta\phi = \pi$ ) that can be resolved unambiguously into  
 203 equation (9), the ambiguity velocity  $V_{bmax}$  is found to be  $c/[4f\Delta t \cos(\beta/2)]$ . However, by  
 204 convention, the ambiguity velocity is given by  $c/(4f\Delta t)$  and therefore the  $1/\cos(\beta/2)$  factor is  
 205 incorporated within the calibration matrix that is used to transform beam velocities to three-  
 206 component Cartesian velocities (see equation (13C)). For single pulse-pairs, the phase shift can  
 207 be kept within the  $[-\pi, +\pi]$  interval by increasing  $\Delta t$ , which in practice is achieved by increasing  
 208 the velocity range specified in MIDAS. Wrapping or aliasing can be identified as a sudden  
 209 jump in velocity, typically with a change of sign (Franca and Lemmin 2006, Hurther *et al*  
 210 2011). Although aliasing should be avoided whenever possible, aliased data may be corrected  
 211 during post-processing by applying unwrappers to raw phase shifts recovered from beam  
 212 velocities. 1-D unwrappers (e.g., Franca and Lemmin 2006, Hurther *et al* 2011) may be applied  
 213 to phase time-series collected by a single beam in a single cell, 2-D unwrappers may be applied  
 214 to phase time-series collected by a single beam in more than one cell, or 3-D unwrappers may  
 215 be applied to phase time-series collected by more than one beam in more than one cell and  
 216 arranged into a 3-D array (e.g., Ghiglia and Pritt 1998, Zappa and Busca 2008, Parkhurst *et al*  
 217 2011).

218 To measure velocities faster than  $V_{bmax}$ , a dual pulse-pair repetition scheme is  
 219 implemented in the Vectrino Profiler. This scheme uses two pulse-pairs with unequal spacing  
 220 in time,  $\Delta t_1$  and  $\Delta t_2$ . To obtain a single velocity measurement with the dual pulse-pair scheme,  
 221 the central transceiver emits three acoustic pulses  $\Delta t_1$  and  $\Delta t_2$  apart, where  $\Delta t_1 < \Delta t_2$ , which  
 222 yield two separate estimates of phase shift,  $\Delta\phi_1$  and  $\Delta\phi_2$ , that are used to estimate the beam  
 223 velocity:

$$225 \quad V_b = \frac{c}{4\pi f} \frac{1}{\cos\left(\frac{\beta}{2}\right)} \frac{(\Delta\phi_2 - \Delta\phi_1)}{(\Delta t_2 - \Delta t_1)} \quad (10)$$

226  
 227 Using unequal pulse-pairs extends the velocity range since the ambiguity velocity is then  
 228 defined by the difference between the pulse-pair intervals:  $c/(4f[\Delta t_2 - \Delta t_1])$ . However, signal  
 229 noise limits the usable time difference (Craig *et al* 2011).

230 Again, multiple sets of dual pulses are averaged to obtain a more reliable estimate of  
 231  $\Delta\phi$ . For a given sampling frequency ( $f_s$ ), the number of pulse-pairs averaged by the Vectrino  
 232 Profiler is given by:

$$233 \quad NPP = \begin{cases} \left\lfloor \frac{f_s}{\Delta t + \Delta t_D} - 2 \right\rfloor & \text{For single pulse pairs} \\ \left\lfloor \frac{f_s}{(\Delta t_1 + \Delta t_2 + \Delta t_D)} - 2 \right\rfloor & \text{For dual pulse pairs} \end{cases} \quad (11)$$

234  
 235 where  $\Delta t_D$  is the dwell time introduced when transmit pulses longer than 1 mm are combined  
 236 with  $\Delta t < 175 \mu s$ , and is normally  $\sim 185 \mu s$  per measurement cycle. The ping interval  $\Delta t$  can  
 237 vary between  $\sim 1300 \mu s$  and  $\sim 108 \mu s$ , with the upper limit being influenced by turbulence  
 238 decorrelation and the lower limit being the shortest time between pulses to prevent echoes from  
 239 adjacent pulses interfering with each other. Note that unlike the Nortek NDV (Nortek 1997),  
 240 no additional computational processing time is required during each measurement cycle. In  
 241 addition, when unequal pulse-pairs are used to measure faster velocities there is a decrease in  
 242  $NPP$  since each velocity calculation requires a separate dual pulse-pair.

## 244 2.4 Ping interval algorithms

245 In MIDAS, three algorithms are available to set the appropriate ping interval,  $\Delta t$ :

- 1  
2  
3 246 A. The maximum interval algorithm selects  $\Delta t$  to achieve the desired ambiguity velocity.  
4  
5 247 If  $2\Delta R_T/c > \Delta t$  where  $\Delta R_T$  is the vertical distance from the transceiver to the centroid  
6  
7 248 of the farthest sampled “cell”, the dual pulse-pair repetition scheme is used to set  $\Delta t_1$   
8  
9 249 and  $\Delta t_2$ . Maximizing  $\Delta t$  is beneficial for data quality, because a larger  $\Delta t$  results in a  
10  
11 250 larger phase difference for a given beam velocity (equations (9) and (10)), increasing  
12  
13 251 the resolution of beam velocity estimates. In the authors’ experience, provided that the  
14  
15 252 flow is well seeded (i.e., correlations  $> 90\%$ , SNRs  $> 30$  dB) and the user has a good *a*  
16  
17 253 *priori* estimate of the largest velocity magnitude, the maximum interval algorithm  
18  
19 254 results in the highest data quality.
- 20  
21 255 B. The minimum interval algorithm estimates  $\Delta t$  as  $2\Delta R_T/c$ , which produces the smallest  
22  
23 256 possible  $\Delta t$  needed to sample within the farthest sampled “cell” and generally results in  
24  
25 257 an ambiguity velocity which is much larger than that entered by the user. Reduced  $\Delta t$   
26  
27 258 yields a smaller phase difference for a given beam velocity (equations (9) and (10)),  
28  
29 259 reducing the resolution of beam velocity estimates. Conversely, by minimizing  $\Delta t$ , the  
30  
31 260 minimum interval algorithm results in a larger number of pulse pairs being averaged  
32  
33 261 together, which reduces electrical noise. Nortek (2015a) suggest that the minimum  
34  
35 262 interval algorithm might be a preferable choice in highly turbulent flow.
- 36  
37 263 C. The adaptive interval algorithm examines profiles of acoustic backscatter from all four  
38  
39 264 receivers and estimates the temporal position of acoustic interference in the backscatter.  
40  
41 265 It then selects  $\Delta t$  to achieve the desired ambiguity velocity and maximum sampling  
42  
43 266 range while minimising/removing acoustic interference. If the environment is likely to  
44  
45 267 change significantly during data collection, the user may request the ping interval to be  
46  
47 268 adjusted dynamically throughout data collection. Despite advice within Nortek’s  
48  
49 269 Software User Guide (Nortek 2015a) that the adaptive interval algorithm “is the best  
50  
51 270 general choice”, in the authors’ experience, it switches too readily between rather high  
52  
53 271 and rather low ambiguity velocities, so that although it may minimise acoustic  
54  
55 272 interference, it results in aliasing and poor data quality.

## 51 273 **2.5 The technical implementation of profiling and its consequences**

52  
53  
54 274 For a non-profiling ADV such as the Vector or Vectrino, a combination of the probe geometry  
55  
56 275 (a bistatic angle,  $\beta/2$ , of  $15^\circ$ ) and the known travel time of the emitted acoustic pulse ensures  
57  
58 276 that the signal is sampled at the sweet spot, where the received signal is at its strongest  
59  
60 277 (McLelland and Nicholas 2000). This part of the signal is then sampled and processed to

278 estimate the time rate of change of phase,  $\Delta\phi/\Delta t$ , using the pulse-pair algorithm (section 3.1,  
 279 Miller and Rochwarger 1972, Zrnic 1977, Lhermitte and Serafin 1984). For a non-profiling  
 280 ADV, the structure of the received signal has been thoroughly explained by McLelland and  
 281 Nicholas (2000, their figure 2). For the Vectrino Profiler, instead of sampling the received  
 282 signal at a single instant in time following pulse emission, the signal is range gated such that it  
 283 is sampled at multiple time delays corresponding to the travel time from the centroid of each  
 284 sampled “cell” (figure 2). The different samples are then processed separately to estimate the  
 285 phase shift  $\Delta\phi$  in each cell and thence the velocity (Lemmin and Roland 1997). After an initial  
 286 peak due to the emission of the acoustic pulse (transmit noise; not shown), the signal strength  
 287 peaks when the reflection from the sampling volume reaches the receivers and then drops  
 288 asymptotically to a background level, corresponding to the (electronic) system noise (figure 2).  
 289 The received signal is not a step function, but instead varies smoothly because of noise and the  
 290 high number of scatterers within the sampling volume (figure 2). Range gating enables beam  
 291 velocity measurements to be measured between 20 and 96 mm below the central transceiver,  
 292 with a transformation to orthogonal velocity components calibrated for a region between 40  
 293 and 74 mm below the transceiver (Craig *et al* 2011). The bistatic angle,  $\beta/2$ , therefore varies  
 294 within the calibrated region, with the ideal value ( $15^\circ$ ) only occurring at the sweet spot ( $\sim 50$   
 295 mm below the transceiver).

296 A combination of the smoothly varying nature of the received signal and these  
 297 geometric considerations cause vertical profiles of the signal-to-noise ratio, SNR, to be  
 298 parabolic, with the peak signal strength and highest SNR occurring at the sweet spot.  
 299 Concurrently, other cells have reduced SNR. SNR (in dB) is the difference between the signal  
 300 strength (in dB) and background noise (in dB):

$$\text{SNR} = \text{signal amplitude} - \text{noise amplitude} \quad (12)$$

304 where the noise amplitude is determined at the start of a measurement by activating the  
 305 receivers without activating the transceiver (Nortek 2012). This approach adequately quantifies  
 306 background noise if that noise is temporally invariant but it is incapable of accounting for  
 307 temporal variations and, crucially, the effects of constructive and destructive interference are  
 308 included within the signal rather than the noise. Thus, measurements that suffer from  
 309 interference may exhibit erroneously large SNR-values, and SNR is not a reliable metric for  
 310 assessing data quality in these circumstances.

311 Nortek state that SNR should be at least 20 dB in distal and proximal cells and at least  
 312 30 dB in the sweet spot (Nortek 2013, MacVicar *et al* 2014). SNR may be improved by  
 313 increasing the power of the emitted pulse or increasing the number of scatterers in the sampling  
 314 volume. The latter may be achieved by either adding seeding particles or increasing the transmit  
 315 pulse size, which is the length of the transmitted acoustic pulse in conjunction with individual  
 316 cell size. Since the sampling volume of an individual cell is  $\pi(d_1^2+d_2^2)L/8$ , where  $d_1$  and  $d_2$  are  
 317 the diameters of the transmitted beam at the top and bottom of a cell and  $L$  is the cell size (=   
 318 cell height), the number of scatterers in the sampling volume increases at least linearly with  
 319 cell size (depending on the beam spread). Within MIDAS, the user may select the cell size to  
 320 be 1, 2, 3 or 4 mm; changing the cell size automatically changes the transmit pulse size to  
 321 match (Nortek 2015a). Increasing cell size and transmit pulse size thus increases the number  
 322 of scatterers contributing to sampled echo and the phase estimate at a specific instant in time.

## 323 2.6 Transformation of beam velocities to three-component velocities

324 Equations (9) and (10) presented how the beam velocity is calculated for a system of one  
 325 transceiver and one receiver. Since the Vectrino Profiler consists of four receivers operating  
 326 simultaneously, four beam velocities are measured, each one being a projection of the true  
 327 velocity vector onto the corresponding bisector (figure 1(b)). The on-axis beam velocities may  
 328 be transformed to a Cartesian reference frame. Conventionally, the streamwise velocity,  $u$ , is  
 329 perpendicular to the probe axis and points in the direction of the first receiver (marked with a  
 330 red collar, figure 3(a)), the vertical velocity,  $w$ , points towards the transceiver, and the cross-  
 331 stream velocity,  $v$ , is perpendicular to both  $u$  and  $w$ , as defined by the right-handed coordinate  
 332 system and points towards the second receiver. For a perfectly manufactured device, receivers  
 333 1 and 3 are coplanar and orthogonal to receivers 2 and 4. Therefore, the first two measure  $u$   
 334 and  $w_1$ , while the latter two measure  $v$  and  $w_2$ , where  $w_1$  and  $w_2$  are independent measurements  
 335 of the vertical velocity. The transformation from beam velocities  $V_{b1}$ ,  $V_{b2}$ ,  $V_{b3}$  and  $V_{b4}$  to  
 336 Cartesian velocities  $u$ ,  $v$ ,  $w_1$  and  $w_2$  is found through multiplication by an appropriate matrix:

$$337 \begin{bmatrix} u_i \\ v_i \\ w_{1,i} \\ w_{2,i} \end{bmatrix} = \mathbf{T}_i \begin{bmatrix} V_{b1,i} \\ V_{b2,i} \\ V_{b3,i} \\ V_{b4,i} \end{bmatrix} \quad (13A)$$

339  
 340 where:

$$\mathbf{T}_i = \begin{bmatrix} a_{11,i} & a_{12,i} & a_{13,i} & a_{14,i} \\ a_{21,i} & a_{22,i} & a_{23,i} & a_{24,i} \\ a_{31,i} & a_{32,i} & a_{33,i} & a_{34,i} \\ a_{41,i} & a_{42,i} & a_{43,i} & a_{44,i} \end{bmatrix} \quad (13B)$$

For a perfectly manufactured device,

$$\mathbf{T}_i = \begin{bmatrix} \frac{\cos(\beta_i/2)}{\sin \beta_i} & 0 & \frac{-\cos(\beta_i/2)}{\sin \beta_i} & 0 \\ 0 & \frac{\cos(\beta_i/2)}{\sin \beta_i} & 0 & \frac{-\cos(\beta_i/2)}{\sin \beta_i} \\ \frac{\cos(\beta_i/2)}{(1 + \cos \beta_i)} & 0 & \frac{\cos(\beta_i/2)}{(1 + \cos \beta_i)} & 0 \\ 0 & \frac{\cos(\beta_i/2)}{(1 + \cos \beta_i)} & 0 & \frac{\cos(\beta_i/2)}{(1 + \cos \beta_i)} \end{bmatrix} \quad (13C)$$

Note that the cell number  $i$  is introduced for the first time here, denoting the  $i^{\text{th}}$  velocity profiling cell away from the transceiver. As cell location determines the angle  $\beta_i$ , each cell has a unique transformation matrix  $\mathbf{T}_i$ . Note also that equation (13C) has been written to explicitly show the  $\cos(\beta_i/2)$  factor from the ambiguity velocity equation and can be simplified through use of the double angle formulae. Due to production tolerances, in practice  $\mathbf{T}_i$  differs somewhat from the ideal values presented in equation (13C) and is obtained through calibration. This calibration is stored within the firmware of each probe in fixed point integer form (R. Craig, personal communication, 18<sup>th</sup> August, 2014), and is part of the MATLAB .mat file exported by MIDAS. When cell sizes larger than 1 mm are used, MIDAS averages the calibration matrices for the 1 mm cells that constitute the larger cells and then truncates the resulting matrix to fixed point integer form (R. Craig, personal communication, 18<sup>th</sup> August, 2014).

### 3 Experimental Methodology

To investigate the behaviour and to assess the performance of the Vectrino Profiler, three separate experiments were performed. First, systematic tests (Experiment 1) were undertaken using a beaker emplaced on a magnetic stirrer to assess the sensitivity of amplitude and correlation to the concentration of acoustic seeding. Second, a flume experiment (Experiment 2) was undertaken to assess the internal consistency of velocities and noise in neighbouring

1  
2  
3 364 cells in a single profile at a range of transceiver power settings and seeding concentrations.  
4  
5 365 Third, a flume experiment (Experiment 3) was undertaken to assess the internal consistency of  
6  
7 366 velocities and noise in neighbouring cells in a single profile at two different flow rates under  
8  
9 367 optimal seeding conditions. All experiments were undertaken with Vectrino Profilers  
10  
11 368 purchased prior to the introduction of modified receiver ceramics and a modified calibration  
12  
13 369 procedure in May 2016. The following sections present the methodologies of all three  
14  
15 370 experiments.

### 16 371 **3.1 Experiment 1: Sensitivity of amplitude and correlation to the concentration of** 17 18 372 **acoustic seeding**

19  
20  
21 373 Tests were undertaken in which the concentration of the acoustic seeding material Talisman 10  
22  
23 374 (specific gravity 0.99), pre-sieved to retain only the portion of the particle size distribution  
24  
25 375 between 20 and 100  $\mu\text{m}$ , was systematically increased in a 6 L beaker that was initially filled  
26  
27 376 with distilled water. A magnetic stirrer was used to maintain the seeding material in suspension.  
28  
29 377 The Vectrino Profiler with probe and hardware serial numbers VCN8374 and VNO1256,  
30  
31 378 respectively, was mounted 200 mm above the bottom of the beaker; the profiling region was  
32  
33 379 thus 126-160 mm above the bottom of the beaker, sufficiently far away to avoid interaction  
34  
35 380 with the stirrer. The vertical location of the probe head was set using the bottom check facility  
36  
37 381 afforded by the Vectrino Profiler ( $\pm 0.1$  mm) and verified using a steel rule ( $\pm 0.5$  mm).  
38  
39 382 Velocities, amplitudes and correlations were monitored at 100 Hz for 240 s, yielding 24,000  
40  
41 383 samples in each cell. The firmware and software was version 1.20.1698, dating from December  
42  
43 384 2012. The ping interval algorithm was set to maximum interval and the velocity range was set  
44  
45 385 to  $0.4 \text{ m s}^{-1}$ , equivalent to a beam ambiguity velocity of  $0.113 \text{ m s}^{-1}$ .

### 46 386 **3.2 Experiment 2: Internal consistency of velocities and noise in neighbouring cells in a** 47 48 387 **single profile at a range of transceiver power settings and seeding concentrations**

49  
50 388 Velocity profiles were sampled at a series of overlapping vertical positions in a  $2.6 \text{ m long} \times$   
51  
52 389  $0.082 \text{ m wide} \times 0.120 \text{ m deep}$  Plexiglas recirculating flume at Ghent University, Belgium. The  
53  
54 390 flume slope was set to  $0 \text{ m m}^{-1}$ , water depth at the measurement location was  $0.114 \text{ m}$  and the  
55  
56 391 discharge was  $0.00116 \text{ m}^3\text{s}^{-1}$ . Velocities were first sampled in ‘clear’ tap water (with no added  
57  
58 392 acoustic seeding material) and tests were undertaken using three different power settings  
59  
60 393 (‘low’, ‘high-’, and ‘high’). Referenced to  $1 \mu\text{Pa}$  at  $1 \text{ m}$ , these settings correspond to emitted  
394 sound intensity levels of 150 dB, 162 dB, and 168 dB, respectively (Poindexter *et al* 2011).

1  
2  
3 395 During a second series of experiments, power was set to ‘high’ and kaolin ( $D_{15} = 0.8 \mu\text{m}$ ,  $D_{85}$   
4 396  $= 1 \mu\text{m}$ ) was suspended in the water until the flow was saturated and SNR remained constant.  
5  
6 397 This condition corresponded to the maximum SNR that could be achieved without continuous  
7  
8 398 feeding of seeding material. Measurements were then repeated with the Vectrino Profiler in the  
9  
10 399 same orientation and also rotated by  $90^\circ$  and  $180^\circ$  relative to the flume axis.

11  
12 400 In both test series, the Vectrino Profiler with probe and hardware serial numbers  
13 401 VCN8472 and VNO1322, respectively, was mounted on a thumb screw with a measurement  
14  
15 402 accuracy of 0.1 mm and set to sample velocities in 16, 2 mm high, cells at 30 Hz for 120  
16  
17 403 seconds at a height of 60 mm above the flume floor. The probe was then moved downwards  
18  
19 404 by 2 mm, corresponding to the height of one cell. As a consequence, the point that was located  
20  
21 405 in the  $i^{\text{th}}$  cell during the first recording was now located in the  $(i-1)^{\text{th}}$  cell. Iteratively, a set of  
22  
23 406 16 measurements was performed in increasingly lower positions, until the 16<sup>th</sup> cell of the first  
24  
25 407 recording was located in the 1<sup>st</sup> cell of the last recording (figure 3(b)). This methodology  
26  
27 408 yielded one vertical location (30 mm above the bottom) in which the velocity was sampled 16  
28  
29 409 times but in different cells (i.e. in different positions relative to the transceiver). If the Vectrino  
30  
31 410 Profiler performed consistently over the entire profile, the 16 evaluations of mean velocities  
32  
33 411 and second order statistics would be equal at this vertical location since the blockage ratio  
34  
35 412 (projected immersed probe area/flume cross-sectional area) only increased from 4.44% to  
36  
37 413 6.69%.

38 414 The firmware and software was version 1.22.1950, dating from August 2013. The ping  
39  
40 415 interval algorithm was set to maximum interval and the velocity range was set to  $0.5 \text{ m s}^{-1}$ ,  
41  
42 416 which was sufficiently high to avoid destructive interference associated with multiple  
43  
44 417 reflections of the emitted sound from the bottom back to the sampling volume and also from  
45  
46 418 the bottom to the water surface and back to the sampling volume (Nortek 2013). Sampled  
47  
48 419 velocities were despiked using the algorithm proposed by Wahl (2003). Typically, the number  
49  
50 420 of detected spikes was low: less than 2% of the collected data.

### 421 **3.3 Experiment 3: Internal consistency of velocities and noise in neighbouring cells in a** 422 **single profile under optimal seeding conditions**

53  
54 423 In this experiment, velocity profiles were sampled at a series of overlapping vertical positions  
55  
56 424 in a 10 m long  $\times$  0.3 m wide  $\times$  0.5 m deep glass-walled Armfield<sup>TM</sup> recirculating flume at the  
57  
58 425 University of Hull, UK. The flume was filled one particle deep with 2-4 mm gravel clasts that  
59  
60 426 were immobile at the imposed flow rates (pump frequencies of 10 Hz and 25 Hz, generating

depth-averaged velocities of 0.118 and 0.331 m s<sup>-1</sup>, respectively) and slope (0 m m<sup>-1</sup>). Mean water depth was held constant across all experiments at 0.15 m and Talisman 10, pre-sieved to retain only the portion of the particle size distribution between 20 and 100 µm, was used to set seeding concentration to 3,000 mg L<sup>-1</sup>. The Vectrino Profiler with probe and hardware serial numbers VCN8374 and VNO1256, respectively, was mounted on a thumb screw and set to sample velocities in 35, 1 mm high, cells at 100 Hz for 240 s. A similar methodology to experiment 2 was adopted, except that 4 mm vertical increments were used and the bottom check facility afforded by the Vectrino Profiler was used to assess those increments. Likewise, if the Vectrino Profiler performed consistently over the entire profile, the nine evaluations of mean velocities and second order statistics would be equal since the blockage ratio (projected immersed probe area/flume cross-sectional area) only increased from 1.29% to 1.85%.

The firmware and software was version 1.20.1698, dating from December 2012. The ping interval algorithm was set to maximum interval and the velocity range was set to 0.3, 1.3 or 2.4 m s<sup>-1</sup> (equivalent to a beam ambiguity velocity of 0.085, 0.185 or 0.342 m s<sup>-1</sup>, respectively), depending on the pump frequency. These velocity ranges were sufficiently high to avoid aliasing and any destructive interference. Sampled velocities were despiked using the algorithm proposed by Wahl (2003); the number of detected spikes was always less than 1% of the collected data.

## 4 Data quality assessment

### 4.1 Quantification and correction of noise

As noted previously, the geometry of a perfectly manufactured Vectrino Profiler yields two independent measurements of the vertical velocity,  $w_1$  and  $w_2$ . Hurther and Lemmin (2001) and Blanckaert and Lemmin (2006) showed that the covariances,  $\overline{uv}$ ,  $\overline{uw_2}$  and  $\overline{vw_1}$ , and variance  $\overline{w_1w_2}$  are free of noise but the variances,  $\overline{u^2}$ ,  $\overline{v^2}$ ,  $\overline{w_1^2}$ , and  $\overline{w_2^2}$  contain noise. In practice, the Vectrino Profiler is unlikely to be perfectly manufactured and these statements may not be true (Brand *et al* 2016). Following Lohrmann *et al* (1995) and Voulgaris and Trowbridge (1998), if equation (13B) is used to expand equation (13A) and it is explicitly recognised that measured beam velocities,  $V_b$ , consist of the true velocity,  $\widehat{V}_b$ , plus unbiased noise,  $n$  (where  $\bar{n} \equiv 0$ ), the following equations are obtained:

$$u_i = a_{11,i}(\widehat{V}_{b1,i} + n_{1,i}) + a_{12,i}(\widehat{V}_{b2,i} + n_{2,i}) + a_{13,i}(\widehat{V}_{b3,i} + n_{3,i}) + a_{14,i}(\widehat{V}_{b4,i} + n_{4,i}) \quad (14A)$$

$$v_i = a_{21,i}(\widehat{V}_{b1,i} + n_{1,i}) + a_{22,i}(\widehat{V}_{b2,i} + n_{2,i}) + a_{23,i}(\widehat{V}_{b3,i} + n_{3,i}) + a_{24,i}(\widehat{V}_{b4,i} + n_{4,i}) \quad (14B)$$

$$w_{1,i} = a_{31,i}(\widehat{V}_{b1,l} + n_{1,i}) + a_{32,i}(\widehat{V}_{b2,l} + n_{2,i}) + a_{33,i}(\widehat{V}_{b3,l} + n_{3,i}) + a_{34,i}(\widehat{V}_{b4,l} + n_{4,i}) \quad (14C)$$

$$w_{2,i} = a_{41,i}(\widehat{V}_{b1,l} + n_{1,i}) + a_{42,i}(\widehat{V}_{b2,l} + n_{2,i}) + a_{43,i}(\widehat{V}_{b3,l} + n_{3,i}) + a_{44,i}(\widehat{V}_{b4,l} + n_{4,i}) \quad (14D)$$

461

462 In the absence of noise, the products  $\overline{w_1^2}$ ,  $\overline{w_1 w_2}$ , and  $\overline{w_2^2}$  are equal. To quantify noise, previous  
 463 investigators (Lohrmann *et al* 1995, Voulgaris and Trowbridge 1998, Hurther and Lemmin  
 464 2001) assumed that noise is independent of the velocity fluctuations, noise fluctuations in  
 465 independent receivers are uncorrelated, and all receivers are identical. If the latter assumption  
 466 is relaxed by assuming that the noise of opposite beams (i.e., beams 1 and 3 and beams 2 and  
 467 4) have identical variances, equations (14C) and (14D) can be used to write:

468

$$\begin{aligned} \overline{w_{1,l}^2} &= a_{31,i}^2 (\overline{\widehat{V}_{b1,l}^2} + \sigma_{13,i}^2) + a_{32,i}^2 (\overline{\widehat{V}_{b2,l}^2} + \sigma_{24,i}^2) + a_{33,i}^2 (\overline{\widehat{V}_{b3,l}^2} + \sigma_{13,i}^2) \\ &+ a_{34,i}^2 (\overline{\widehat{V}_{b4,l}^2} + \sigma_{24,i}^2) + 2a_{31,i}a_{32,i}\overline{\widehat{V}_{b1,l}\widehat{V}_{b2,l}} + 2a_{31,i}a_{33,i}\overline{\widehat{V}_{b1,l}\widehat{V}_{b3,l}} \\ &+ 2a_{31,i}a_{34,i}\overline{\widehat{V}_{b1,l}\widehat{V}_{b4,l}} + 2a_{32,i}a_{33,i}\overline{\widehat{V}_{b2,l}\widehat{V}_{b3,l}} + 2a_{32,i}a_{34,i}\overline{\widehat{V}_{b2,l}\widehat{V}_{b4,l}} \\ &+ 2a_{33,i}a_{34,i}\overline{\widehat{V}_{b3,l}\widehat{V}_{b4,l}} \end{aligned} \quad (15A)$$

474

$$\begin{aligned} \overline{w_{1,l}w_{2,l}} &= a_{31,i}a_{41,i} (\overline{\widehat{V}_{b1,l}^2} + \sigma_{13,i}^2) + a_{32,i}a_{42,i} (\overline{\widehat{V}_{b2,l}^2} + \sigma_{24,i}^2) \\ &+ a_{33,i}a_{43,i} (\overline{\widehat{V}_{b3,l}^2} + \sigma_{13,i}^2) + a_{34,i}a_{44,i} (\overline{\widehat{V}_{b4,l}^2} + \sigma_{24,i}^2) \\ &+ (a_{31,i}a_{42,i} + a_{32,i}a_{41,i})\overline{\widehat{V}_{b1,l}\widehat{V}_{b2,l}} + (a_{31,i}a_{43,i} + a_{33,i}a_{41,i})\overline{\widehat{V}_{b1,l}\widehat{V}_{b3,l}} \\ &+ (a_{31,i}a_{44,i} + a_{34,i}a_{41,i})\overline{\widehat{V}_{b1,l}\widehat{V}_{b4,l}} + (a_{33,i}a_{42,i} + a_{32,i}a_{43,i})\overline{\widehat{V}_{b2,l}\widehat{V}_{b3,l}} \\ &+ (a_{32,i}a_{44,i} + a_{34,i}a_{42,i})\overline{\widehat{V}_{b2,l}\widehat{V}_{b4,l}} + (a_{33,i}a_{44,i} + a_{34,i}a_{43,i})\overline{\widehat{V}_{b3,l}\widehat{V}_{b4,l}} \end{aligned} \quad (15B)$$

481

$$\begin{aligned} \overline{w_{2,l}^2} &= a_{41,i}^2 (\overline{\widehat{V}_{b1,l}^2} + \sigma_{13,i}^2) + a_{42,i}^2 (\overline{\widehat{V}_{b2,l}^2} + \sigma_{24,i}^2) + a_{43,i}^2 (\overline{\widehat{V}_{b3,l}^2} + \sigma_{13,i}^2) \\ &+ a_{44,i}^2 (\overline{\widehat{V}_{b4,l}^2} + \sigma_{24,i}^2) + 2a_{41,i}a_{42,i}\overline{\widehat{V}_{b1,l}\widehat{V}_{b2,l}} + 2a_{41,i}a_{43,i}\overline{\widehat{V}_{b1,l}\widehat{V}_{b3,l}} \\ &+ 2a_{41,i}a_{44,i}\overline{\widehat{V}_{b1,l}\widehat{V}_{b4,l}} + 2a_{42,i}a_{43,i}\overline{\widehat{V}_{b2,l}\widehat{V}_{b3,l}} + 2a_{42,i}a_{44,i}\overline{\widehat{V}_{b2,l}\widehat{V}_{b4,l}} \\ &+ 2a_{43,i}a_{44,i}\overline{\widehat{V}_{b3,l}\widehat{V}_{b4,l}} \end{aligned} \quad (15C)$$

487

488 where  $\sigma_{13}^2 = \overline{n_1^2} = \overline{n_3^2}$  and  $\sigma_{24}^2 = \overline{n_2^2} = \overline{n_4^2}$ . Equations for the other variances and covariances  
 489 are provided in the Appendix. In all cases, the first four terms involve the total variance of the  
 490 measured velocity and the last six terms contain cross-products between beams to which the  
 491 uncorrelated Doppler noise has no contribution. The sums of the cross-multiplied calibration  
 492 matrix elements  $\sum_{j=1}^{j=4} a_{1j}^2$ ,  $\sum_{j=1}^{j=4} a_{1j}a_{2j}$ ,  $\sum_{j=1}^{j=4} a_{1j}a_{3j}$ ,  $\sum_{j=1}^{j=4} a_{1j}a_{4j}$ ,  $\sum_{j=1}^{j=4} a_{2j}^2$ ,  $\sum_{j=1}^{j=4} a_{2j}a_{3j}$ ,  
 493  $\sum_{j=1}^{j=4} a_{2j}a_{4j}$ ,  $\sum_{j=1}^{j=4} a_{3j}^2$ ,  $\sum_{j=1}^{j=4} a_{3j}a_{4j}$ , and  $\sum_{j=1}^{j=4} a_{4j}^2$ , dictate how noise is propagated into  
 494 variance and covariance estimates. The magnitudes of these “noise multipliers” are shown in  
 495 table 1 for an example probe. It is clear that for this example probe,  $\overline{uv}$  is not noise free for  
 496 much of the sampled profile, but that the magnitude of the noise in  $\overline{u^2}$  and  $\overline{v^2}$  is 25 to 39 times  
 497 that in  $\overline{uv}$ , and 11 to 16 times that in  $\overline{w_1^2}$  and  $\overline{w_2^2}$ . Conversely,  $\overline{w_1 w_2}$  is virtually noise free  
 498 (maximum noise multiplier = 0.005).

499 The differences  $\overline{w_1^2} - \overline{w_1 w_2}$  and  $\overline{w_2^2} - \overline{w_1 w_2}$  can be used to quantify the noise  
 500 associated with the two independent measurements of the variance of vertical velocity:

$$\begin{aligned}
 501 & \overline{w_{1,l}^2} - \overline{w_{1,l}w_{2,l}} \\
 502 & = \overbrace{\overline{w_{1,l}^2} - \overline{w_{1,l}w_{2,l}}}^{=0} + [a_{31,i}(a_{31,i} - a_{41,i}) + a_{33,i}(a_{33,i} - a_{43,i})]\sigma_{13,i}^2 \\
 503 & + [a_{32,i}(a_{32,i} - a_{42,i}) + a_{34,i}(a_{34,i} - a_{44,i})]\sigma_{24,i}^2 \\
 504 & \\
 505 & \hspace{15em} (16A)
 \end{aligned}$$

$$\begin{aligned}
 506 & \overline{w_{2,l}^2} - \overline{w_{1,l}w_{2,l}} \\
 507 & = \overbrace{\overline{w_{2,l}^2} - \overline{w_{1,l}w_{2,l}}}^{=0} + [a_{41,i}(a_{41,i} - a_{31,i}) + a_{43,i}(a_{43,i} - a_{33,i})]\sigma_{13,i}^2 \\
 508 & + [a_{42,i}(a_{42,i} - a_{32,i}) + a_{44,i}(a_{44,i} - a_{34,i})]\sigma_{24,i}^2 \\
 509 & \\
 510 & \hspace{15em} (16B)
 \end{aligned}$$

511 where the circumflexes are used to denote the noise-free terms in equations (15A) to (15C).  
 512 Consideration of the magnitudes of the terms in equations (16) indicates that equation (16A) is  
 513 dominated by terms associated with beams 1 and 3, and equation (16B) is dominated by terms  
 514 associated with beams 2 and 4. Nevertheless, after substitution and elimination,  
 515

$$\begin{aligned}
517 \quad & \sigma_{13,i}^2 \\
518 \quad & = \frac{[a_{42,i}(a_{42,i} - a_{32,i}) + a_{44,i}(a_{44,i} - a_{34,i})](\overline{w_{1,l}^2} - \overline{w_{1,l}w_{2,l}}) - [a_{32,i}(a_{32,i} - a_{42,i}) + a_{34,i}(a_{34,i} - a_{44,i})](\overline{w_{2,l}^2} - \overline{w_{1,l}w_{2,l}})}{\left( [a_{31,i}(a_{31,i} - a_{41,i}) + a_{33,i}(a_{33,i} - a_{43,i})][a_{42,i}(a_{42,i} - a_{32,i}) + a_{44,i}(a_{44,i} - a_{34,i})] - [a_{41,i}(a_{41,i} - a_{31,i}) + a_{43,i}(a_{43,i} - a_{33,i})][a_{32,i}(a_{32,i} - a_{42,i}) + a_{34,i}(a_{34,i} - a_{44,i})] \right)} \\
519 \quad & \quad \quad \quad (17A)
\end{aligned}$$

$$\begin{aligned}
521 \quad & \sigma_{24,i}^2 \\
522 \quad & = \frac{[a_{31,i}(a_{31,i} - a_{41,i}) + a_{33,i}(a_{33,i} - a_{43,i})](\overline{w_{2,l}^2} - \overline{w_{1,l}w_{2,l}}) - [a_{41,i}(a_{41,i} - a_{31,i}) + a_{43,i}(a_{43,i} - a_{33,i})](\overline{w_{1,l}^2} - \overline{w_{1,l}w_{2,l}})}{\left( [a_{31,i}(a_{31,i} - a_{41,i}) + a_{33,i}(a_{33,i} - a_{43,i})][a_{42,i}(a_{42,i} - a_{32,i}) + a_{44,i}(a_{44,i} - a_{34,i})] - [a_{41,i}(a_{41,i} - a_{31,i}) + a_{43,i}(a_{43,i} - a_{33,i})][a_{32,i}(a_{32,i} - a_{42,i}) + a_{34,i}(a_{34,i} - a_{44,i})] \right)} \\
523 \quad & \quad \quad \quad (17B)
\end{aligned}$$

524 Equations (17) quantify the noise associated with the longitudinal tristatic system  
525 (transceiver plus receivers 1 and 3) and the lateral tristatic system (transceiver plus receivers 2  
526 and 4), respectively. They are more applicable to the Vectrino Profiler (and also the Vectrino)  
527 than the approach of Hurther and Lemmin (2001) and Blanckaert and Lemmin (2006), since  
528 angular variations imposed during manufacturing are explicitly included through use of the  
529 calibration matrix. In addition, although it is most likely that the noise variances of all beams  
530 are unequal, the assumption that the noise variances of opposite beams are equal is less  
531 restrictive than that imposed in previous work (e.g. Lohrmann *et al* 1995, Voulgaris and  
532 Trowbridge 1998, Hurther and Lemmin 2001). The resulting noise estimates can be combined  
533 with information held in the calibration matrix to estimate noise-corrected values of the  
534 variances,  $\overline{u^2}$ ,  $\overline{v^2}$ ,  $\overline{w_1^2}$ ,  $\overline{w_2^2}$ , and  $\overline{w_1w_2}$ , and covariances,  $\overline{uv}$ ,  $\overline{uw_1}$ ,  $\overline{uw_2}$ ,  $\overline{vw_1}$ , and  $\overline{vw_2}$ ,  
535 respectively.

## 536 4.2 Temporal convergence

537 The sampling period  $T$  necessary to yield given relative errors in the time averages, variances,  
538  $\overline{u^2}$ ,  $\overline{v^2}$ , and  $\overline{w^2}$ , and covariances,  $\overline{uv}$ ,  $\overline{uw}$ , and  $\overline{vw}$ , may be estimated by first estimating the  
539 number of independent velocity samples, given by  $T/2\tau$ , where  $\tau$  is the integral time scale of  
540 the local flow field given by integrating the temporal autocorrelation coefficient (Tennekes and  
541 Lumley 1972):

542

$$\tau_u = \int_0^\infty \frac{\overline{u(t)u(t+\Delta t)}}{u^2(t)} d\Delta t \quad (18)$$

544

545 where the subscript  $u$  on  $\tau$  explicitly recognises that the integral time scale for each velocity  
 546 component, product and cross-product are not necessarily equal (Soulsby 1980) and  $\Delta t$  is a  
 547 time delay. Note that equation (18) has been written for the  $u$  velocity component but can  
 548 similarly be written for the  $v$  and  $w$  components. Combining equations given by Bendat and  
 549 Piersol (1986: 288), Benedict and Gould (1996: 131), and Garcia *et al* (2006: 516), for a given  
 550 relative root mean square error,  $\varepsilon$ ,  $T$  may be estimated by:

551

$$T_{\bar{u}} \cong \frac{2\tau_u \bar{u}^2}{\varepsilon^2 \bar{u}^2} \quad (19A)$$

$$T_{\bar{u}^2} \cong \frac{2\tau_{u^2}}{\varepsilon^2} \left[ \frac{u^4 - (\bar{u}^2)^2}{(\bar{u}^2)^2} \right] \quad (19B)$$

$$T_{\bar{uv}} \cong \frac{2\tau_{uv}}{\varepsilon^2} \left[ \frac{u^2 v^2 - (\bar{uv})^2}{(\bar{uv})^2} \right] \quad (19C)$$

555

556 where equations (19A)-(19C) have been written for  $\bar{u}$ ,  $\bar{u}^2$ , and  $\bar{uv}$ , but again could be written  
 557 for the other components. Note that we can expect that  $T_{\bar{uv}} > T_{\bar{u}^2} > T_{\bar{u}}$  (e.g. Soulsby 1980).  
 558 Confidence intervals on the time averages may be estimated using the standard deviations, a  
 559 one-sided student's t table and setting the number of samples equal to, for example,  $T/2\tau_u$ ,  
 560 whereas confidence intervals on the (co)variances may be estimated using the (co)variances  
 561 themselves, a two-sided student's t table and setting the number of samples equal to, for  
 562 example,  $T/2\tau_{\bar{u}^2}$  (Benedict and Gould 1996).

## 563 5 Results

### 564 5.1 Experiment 1: Sensitivity of amplitude and correlation to the concentration of 565 acoustic seeding

566 Figures 4 and 5 show the impact of varying the concentration of acoustic seeding on the vertical  
 567 variation of mean amplitude for 1 mm and 4 mm high cells, respectively. Mean amplitude  
 568 varies parabolically, with a maximum at the sweet spot 50 mm below the transceiver and a  
 569 reduction above and below that location, with a very slight decrease in the rate of reduction  
 570 further away from the receiver (figure 4). This parabolic form is as expected, and is caused by  
 571 the combination of the smoothly varying nature of the received signal and the vertical variation

1  
2  
3 572 of the bistatic angle. As the concentration of acoustic seeding is increased, the pattern of change  
4  
5 573 becomes smoother, the maximum gets larger, the peak is broadened (i.e., the sweet spot is  
6  
7 574 lengthened) and the reduction of amplitude above the sweet spot is lessened (figure 4). The  
8  
9 575 spatial variability for 4 mm high cells is similar to that for 1 mm high cells, but the increased  
10  
11 576 spatial averaging results in less attenuation of mean amplitude, especially towards the top of  
12  
13 577 the profile (figure 5).

14 578 These spatial trends have a strong influence on the vertical variation of the correlation  
15  
16 579 coefficient (figures 6 and 7). In particular, there is a significant decrease in correlation for  
17  
18 580 concentrations  $< 3,000 \text{ mg L}^{-1}$  (figure 6). Interestingly, correlation is increased at the sweet  
19  
20 581 spot at low-to-medium concentrations and actually decreases for higher concentrations (figures  
21  
22 582 6 and 7), with an optimum concentration of seeding of between 3,000 and 6,000  $\text{mg L}^{-1}$ .  
23  
24 583 Scattering and attenuation become significant at concentrations  $> 20,000 \text{ mg L}^{-1}$ , effectively  
25  
26 584 modifying the geometry shown in figure 1 and invalidating the calibration (A. Lohrmann,  
27  
28 585 personal communication, 22<sup>nd</sup> October, 2015). In addition, correlation is generally larger above  
29  
30 586 the sweet spot for 4 mm high cells than for 1 mm high cells but it is generally smaller below  
31  
32 587 the sweet spot for 4 mm high cells than for 1 mm high cells (figures 6 and 7). Consideration of  
33  
34 588 the form of the correlation profiles suggests that reliable velocity data are most likely to be  
35  
36 589 collected in the region between 43 and 60 mm below the transceiver, with less reliable data  
37  
38 590 more likely with greater distance from this region, and that reliability will degrade further for  
39  
40 591 lower concentrations of acoustic scatterers.

## 39 592 **5.2 Experiment 2: Internal consistency of velocities and noise in neighbouring cells in a** 40 41 593 **single profile at a range of transceiver power settings and seeding concentrations**

42  
43 594 Figure 8(a) illustrates the vertical variation of mean streamwise velocity with cell  
44  
45 595 number, measured at a constant height of 30 mm above the flume floor, for a range of power  
46  
47 596 settings. It is apparent that, contrary to expectation, mean streamwise velocity is not constant  
48  
49 597 with cell number and varies by  $\pm 10\%$ , despite the absolute position of the sampling volume  
50  
51 598 remaining constant (figure 8(a)). For all power settings and seeding concentrations, higher  
52  
53 599 velocity magnitudes were recorded at proximal cells than at the sweet spot, while lower  
54  
55 600 magnitudes were recorded at distal cells than at the sweet spot (figure 8(a)). The same trends  
56  
57 601 are present for measurements repeated with the probe oriented at  $90^\circ$  and  $180^\circ$  to the flume  
58  
59 602 channel axis at 'high' power and saturated seeding concentrations (note that in all cases,  
60  
603 603 velocities have been transformed so that they have the same direction as the measurement

1  
2  
3 604 undertaken at  $0^\circ$ ) (figure 8(a)). The  $90^\circ$  and  $180^\circ$  rotated series highlight that the velocity  
4  
5 605 magnitude is biased, i.e. distal cells are biased towards zero irrespective of whether positive or  
6  
7 606 negative velocities are measured (figure 8(a)). The impact of the power setting on velocity bias  
8  
9 607 is most significant for the distal cells when using 'low' power settings and 'clear' water  
10  
11 608 conditions (figure 8(a)).

12 609 Figure 8(b) shows the vertical variation with cell number of noise on the longitudinal  
13  
14 610 tristatic system, estimated using equation (17A), measured at a constant height of 30 mm above  
15  
16 611 the flume floor, for a range of power settings. Noise varies parabolically, increasing from a  
17  
18 612 minimum at the sweet spot to cells that are proximal and distal to the transceiver (figure 8(b)).  
19  
20 613 For the high power setting, noise is larger in distal cells than lower power settings, whereas the  
21  
22 614 power setting does not appear to impact upon noise in proximal cells (figure 8(b)). Adding  
23  
24 615 kaolin reduces noise but probe orientation does not have a consistent effect on noise. Note that  
25  
26 616 the longitudinal tristatic system at an orientation of  $90^\circ$  is the lateral tristatic system at an  
27  
28 617 orientation of  $0^\circ$  and the lateral tristatic system at an orientation of  $90^\circ$  is the longitudinal  
29  
30 618 tristatic system at an orientation of  $0^\circ$ . Figure 8(d) shows the vertical variation of noise on the  
31  
32 619 lateral tristatic system, estimated using equation (17B). The noise on the lateral tristatic system  
33  
34 620 is 33-50% of the noise on the longitudinal tristatic system, and exhibits significantly less  
35  
36 621 variation than the noise on the longitudinal tristatic system (figure 8(d)). The parabolic form  
37  
38 622 can be explained by the vertical variation of SNR (figure 8(c)), which has a maximum at the  
39  
40 623 sweet spot and then reduces to cells that are proximal and distal to the transceiver. SNR is  
41  
42 624 defined as signal amplitude minus noise amplitude (equation 12). But, following Zedel (2008),  
43  
44 625 the signal amplitude contains both the true signal due to coherent backscatter and incoherent  
45  
46 626 backscatter caused by temporal variations (i.e., random (turbulent) motions) and changes in  
47  
48 627 backscatter strength caused by beam divergence and mean velocity gradients in the sampling  
49  
50 628 volume (Voulgaris and Trowbridge 1998, McLelland and Nicholas 2000). Thus,  $\sigma_{13}^2$  and  $\sigma_{24}^2$   
51  
52 629 equate to the sum of the noise due to incoherent backscatter and the noise amplitude for the  
53  
54 630 longitudinal and lateral tristatic systems, respectively; for a given power level,  $\sigma_{13}^2$  and  $\sigma_{24}^2$   
55  
56 631 must be inversely proportional to SNR. Furthermore, since the noise amplitude can be assumed  
57  
58 632 constant for given seeding concentrations, it is unsurprising that SNR increased with increasing  
59  
60 633 power level (figure 8(c)). Similarly, adding kaolin increased SNR further, but had the largest  
634  
635 634 effect when the probe was oriented at  $0^\circ$  to the flume axis (figure 8(c)). Consideration of figures  
636  
637 635 8(b) and 8(c) implies a threshold SNR above which the effects of noise can be minimised. This  
638  
639 636 threshold varies from about 25 dB at the sweet spot to about 35 dB in proximal and distal cells.

637 These values are significantly more conservative than those recommended by Nortek  
638 (NortekUSA 2013, MacVicar *et al* 2014).

### 639 **5.3 Experiment 3: Internal consistency of velocities and noise in neighbouring cells in a** 640 **single profile under optimal seeding conditions**

641 Figure 9a illustrates the vertical variation of mean streamwise velocity with cell  
642 number, measured at a constant height of 30 mm above the flume floor, for a range of ambiguity  
643 velocities and a pump setting of 10 Hz. This pump setting yielded a mean streamwise velocity  
644 of  $0.105 \text{ m s}^{-1}$  at the sweet spot. As in figure 8(a), mean streamwise velocity was not constant  
645 with cell number, and varied by  $\pm 10\%$  despite the absolute position of the sampling volume  
646 remaining constant (figure 9(a)). However, the form of that variation is not the same as that  
647 exhibited by the probe that collected the data in figure 8(a), with velocity magnitudes similar  
648 to those at the sweet spot recorded in proximal cells and lower velocity magnitudes recorded  
649 in distal cells than at the sweet spot (figure 9(a)). Ambiguity velocity does not appear to have  
650 a significant impact upon the mean streamwise velocity, since the selected ambiguity velocities  
651 prevented any aliasing.

652 Figure 9(b) shows the vertical variation with cell number of noise, normalised by the  
653 noise-free variance of the vertical velocity, on the longitudinal tristatic system, estimated using  
654 equation (17A), measured at a constant height of 30 mm above the flume floor. Similar to the  
655 form exhibited by the probe that was used to collect the data in figure 8(b), noise varies  
656 parabolically, increasing from a minimum at the sweet spot to cells that are proximal and distal  
657 to the transceiver (figure 9(b)). Figure 9(d) shows the vertical variation of noise, normalised by  
658 the noise-free variance of the vertical velocity, on the lateral tristatic system, estimated using  
659 equation (17B). In contrast to the probe that was used to collect the data in figure 8, the noise  
660 on the lateral tristatic system is only marginally less than the noise on the longitudinal tristatic  
661 system, and exhibits a similar parabolic form (figure 9(d)). The parabolic form can again be  
662 explained by the vertical variation of SNR (figure 9(c)), which has a maximum at the sweet  
663 spot and then reduces to cells that are proximal and distal to the transceiver (figure 9(c)). In  
664 both figures 9(b) and 9(d), it is noticeable that noise distal to the transceiver is significantly  
665 larger for the case when the ambiguity velocity was  $0.343 \text{ m s}^{-1}$ . This ambiguity velocity  
666 invoked the dual pulse-pair repetition scheme, which is inherently noisier than the single pulse-  
667 pair scheme (e.g., Holleman and Beekhuis 2003, Joe and May 2003).

1  
2  
3 668 Figure 10(a) illustrates the vertical variation of mean streamwise velocity with cell  
4  
5 669 number, measured at a constant height of 30 mm above the flume floor, for a range of ambiguity  
6  
7 670 velocities and a pump setting of 25 Hz. This pump setting yielded a mean streamwise velocity  
8  
9 671 of  $0.30 \text{ m s}^{-1}$  at the sweet spot. As in figures 8(a) and 9(a), mean streamwise velocity was not  
10  
11 672 constant with cell number, and varied by  $\pm 10\%$  despite the absolute position of the sampling  
12  
13 673 volume remaining constant (figure 10(a)). The form of the variation matched that in figure 9(a),  
14  
15 674 with velocity magnitudes similar to those at the sweet spot recorded in proximal cells and lower  
16  
17 675 velocity magnitudes recorded in distal cells than at the sweet spot (figure 10(a)). Once again,  
18  
19 676 ambiguity velocity does not appear to have a significant impact upon the mean streamwise  
20  
21 677 velocity, since the selected ambiguity velocities prevented any phase wrapping.

22  
23 678 Figures 10(b) and 10(d) show the vertical variation with cell number of noise,  
24  
25 679 normalised by the noise-free variance of the vertical velocity, on the longitudinal and lateral  
26  
27 680 tristatic systems, respectively, estimated using equations (17A) and (17B), respectively. Noise  
28  
29 681 varied parabolically and with a similar magnitude relative to the variance of the vertical  
30  
31 682 velocity as that shown in figures 9(b) and 9(d); both the noise components and  $\overline{w_1 w_2}$  were 6-7  
32  
33 683 times larger for the cases in figure 10 than those in figure 9. SNR was almost identical for the  
34  
35 684 two sets of experiments (figures 9(c) and 10(c)). Voulgaris and Trowbridge (1998) and  
36  
37 685 McLelland and Nicholas (2000) showed that noise contains contributions from both Doppler  
38  
39 686 broadening and the mean velocity gradient in the sampling volume. The dominant component  
40  
41 687 of Doppler broadening is due to turbulence and is assumed proportional to the cube root of the  
42  
43 688 turbulence dissipation rate (Voulgaris and Trowbridge 1998) or the root mean square (rms) of  
44  
45 689 the on-axis radial velocity (= beam velocity, McLelland and Nicholas 2000), which may be  
46  
47 690 approximated by the rms of the vertical velocity. However, the rms of the vertical velocity,  
48  
49 691  $\overline{w_1 w_2}^{1/2}$ , was only 2-3 times larger for the cases in figure 10 than those in figure 9, implying  
50  
51 692 that the noise terms are not proportional to rms for these cases. In contrast to figures 9(b) and  
52  
53 693 9(d), the noise for an ambiguity velocity of  $0.343 \text{ m s}^{-1}$  (dual pulse-pair algorithm) was not  
54  
55 694 significantly greater than that of an ambiguity velocity of  $0.185 \text{ m s}^{-1}$  (single pulse-pair  
56  
57 695 algorithm) (figures 10(b) and 10(d)), which implies that Doppler broadening is not the  
58  
59 696 dominant component of the noise associated with the dual pulse-pair algorithm.

60  
61  
62  
63  
64  
65  
66  
67  
68  
69  
700 Figure 11 illustrates the vertical variation of the time-averaged beam velocities with  
position number, measured at a constant height of 30 mm above the flume floor, for a range of  
ambiguity velocities and pump settings of 10 Hz (figure 11(a)) and 25 Hz (figure 11(b)),  
respectively. It is clear that beam velocities are also not constant with cell number and vary by

701  $\pm 10\text{-}16\%$ , with magnitudes that are larger proximal to the transceiver and smaller distal to the  
 702 transceiver (figure 11). The lack of symmetry of  $V_{b2}$  and  $V_{b4}$  about a velocity of  $0 \text{ m s}^{-1}$  implies  
 703 that there was slight misalignment of the probe with the flume axis (figure 11). In addition,  
 704 deviations of  $V_{b1}$  from its otherwise near-linear trend in the vertical are not necessarily reflected  
 705 in deviations of  $V_{b3}$  and deviations of  $V_{b2}$  from its otherwise near-linear trend in the vertical are  
 706 not necessarily reflected in deviations of  $V_{b4}$ ; note especially the disparity in behaviour  
 707 proximal to the transceiver (figure 11). Furthermore, for the 25 Hz case (figure 11(b)), there  
 708 appears to be a waviness superimposed upon an otherwise linear decrease of  $V_{b3}$  from proximal  
 709 to distal. Ambiguity velocity does not appear to have a significant impact upon the time-  
 710 averaged beam velocities, since the selected ambiguity velocities prevented any aliasing (figure  
 711 11).

#### 712 5.4 Assessment of the noise correction method (equations (17))

713 Figure 12 compares the effectiveness of the noise correction method derived herein (equations  
 714 (17)) against that of Hurther and Lemmin (2001) for the clear water, high power case of  
 715 Experiment 2. All subplots show the vertical variation of noise-related variables with cell  
 716 number, measured at a constant height of 30 mm above the flume floor. While equations (17)  
 717 provide noise estimates for both the longitudinal and lateral tristatic systems,  $\sigma_{13}^2$  and  $\sigma_{24}^2$ , the  
 718 Hurther and Lemmin (2001) method averages the noise over all receivers (figure 12(a)) and  
 719 sets  $\sigma^2 = (\overline{w_1^2} + \overline{w_2^2} - 2\overline{w_1 w_2})/2$  (Blanckaert and Lemmin 2006).  $\sigma^2$  is overdetermined  
 720 because  $\sigma^2$  can be estimated by imposing that any of  $\overline{w_1^2}$ ,  $\overline{w_2^2}$  or  $\overline{w_1 w_2}$  are equal. This  
 721 overdetermination means that, while equations (17) rigorously impose  $\overline{w_1^2} = \overline{w_2^2} = \overline{w_1 w_2}$   
 722 throughout the profile, the method of Hurther and Lemmin (2001) cannot (figure 12(b)).  
 723 Therefore, although the Hurther and Lemmin (2001) method reduces the noise on  $\overline{w_1^2}$  and  $\overline{w_2^2}$ ,  
 724 it does not change the relative difference  $(\overline{w_1^2} - \overline{w_2^2})/\overline{w_1 w_2}$ . This is because, under the  
 725 assumption of identical and ideal receivers, the noise corrections for  $\overline{w_1^2}$  and  $\overline{w_2^2}$ ,  
 726  $(a_{31}^2 + a_{33}^2)\sigma^2$  and  $(a_{42}^2 + a_{44}^2)\sigma^2$ , respectively, are equal and thus cancel. The inability  
 727 to impose  $\overline{w_1^2} = \overline{w_2^2} = \overline{w_1 w_2}$  is especially relevant for the distal cells of the profile, where the  
 728 noise on the two orthogonal tristatic systems differs considerably (figure 12(a)), emphasising  
 729 that the assumption of equal noise on all receivers is not valid. Figures 12(c) and 12(d) show  
 730 that equations (17) apply a larger correction to the longitudinal tristatic system (figure 12(c))  
 731 and a smaller correction to the lateral tristatic system (figure 12(d)), but the Hurther and

1  
2  
3 732 Lemmin (2001) method applies an equal correction to both systems. This is insignificant at the  
4  
5 733 sweet spot, where both methods provide similar noise estimates, but may be important in  
6  
7 734 proximal and distal cells where the Hurther and Lemmin (2001) method may underestimate  
8  
9 735 the noise on one system and overestimate it on the other. For our example case, if it assumed  
10  
11 736 that  $\overline{u^2}$  and  $\overline{v^2}$  are least noisy at the sweet spot (e.g. Brand *et al* 2016), equations (17) provide  
12  
13 737 significantly improved noise estimates for  $\overline{u^2}$  relative to the Hurther and Lemmin (2001)  
14  
15 738 method (figure 12(c)). For  $\overline{v^2}$ , equations (17) provide similar noise estimates to the Hurther  
16  
17 739 and Lemmin (2001) method in proximal cells to 58 mm below the transceiver but  
18  
19 740 underestimate noise in distal cells (figure 12(d)).

## 20 741 **6 Discussion**

21  
22  
23 742 This section explores two key observations. First, mean velocities sampled by the Vectrino  
24  
25 743 Profiler are biased, such that velocity magnitudes are biased by variable amounts in cells  
26  
27 744 proximal to the transceiver, while velocity magnitudes are consistently underestimated in cells  
28  
29 745 distal to the transceiver (figures 8-10(a) and 11). Second, vertical profiles of the noise on the  
30  
31 746 longitudinal and lateral tristatic systems,  $\sigma_{13}^2$  and  $\sigma_{24}^2$ , respectively, are parabolic with a  
32  
33 747 minimum at the sweet spot (figures 8-10(b) and (d)), where signal amplitude, SNR and  $R^2$  all  
34  
35 748 reach their maxima (figures 4-6).

### 36 749 **6.1 Bias in mean velocity estimates**

37  
38  
39 750 Since the release of the Vectrino Profiler in 2010, many scientists (e.g., Zedel and Hay 2011,  
40  
41 751 Ursic *et al* 2012, MacVicar *et al* 2014) and many users who have posted on the knowledge  
42  
43 752 center section of Nortek's website ([http://www.nortek-as.com/en/knowledge-](http://www.nortek-as.com/en/knowledge-center/forum/vectrinoii)  
44  
45 753 [center/forum/vectrinoii](http://www.nortek-as.com/en/knowledge-center/forum/vectrinoii)) have reported that overlapping mean velocity and variance and  
46  
47 754 covariance profiles do not match perfectly. Since (assumed random) noise does not contribute  
48  
49 755 to mean velocity estimates, noise cannot explain the bias on mean velocities. The extent of the  
50  
51 756 bias varies for different probes (compare figures 8-10(a)), which implies that either the quality  
52  
53 757 of individual probes varies or the calibration that transforms beam velocities to orthogonal  
54  
55 758 velocities differs in quality. Figure 11 shows that beam velocities are not constant with cell  
56  
57 759 number and vary by  $\pm 10$ -16%, with magnitudes that are larger proximal to the transceiver,  
58  
59 760 smaller distal to the transceiver and waviness superimposed over the otherwise linear trend  
60  
761 (figure 11(b)). This implies that bias is inherent to the probe geometry and that such bias cannot

1  
2  
3 762 be removed by a transformation matrix that varies linearly with distance from the transceiver  
4  
5 763 (contrast this with the ADVP of Hurther and Lemmin, 2001). Figures 9-10(a) and 11 show that  
6  
7 764 rather than removing bias, application of the transformation matrix propagates that bias and  
8  
9 765 imposes additional curvature on streamwise velocity profiles. Lohrmann (personal  
10  
11 766 communication, 22<sup>nd</sup> October, 2015) reported that the calibration procedure that had initially  
12  
13 767 been implemented by Nortek, towing a probe at  $\pm 0.2 \text{ m s}^{-1}$  in a tank of relatively limited  
14  
15 768 dimensions, made invalid assumptions about the flow field around the probe. Specifically, he  
16  
17 769 showed that the probe head deflects flow when it is towed, which explains why the calibration  
18  
19 770 varied with tow velocity (Ursic *et al* 2012). In response to this, together with the observation  
20  
21 771 that velocities outputted by the Vectrino Profiler were in error by an average of 1.5% and a  
22  
23 772 maximum of 5% at a tow speed of  $\pm 0.6 \text{ m s}^{-1}$ , Nortek modified the calibration procedure in  
24  
25 773 May 2016 so that it is now undertaken by towing a probe at  $\pm 0.2$ ,  $\pm 0.5$  and  $\pm 0.8 \text{ m s}^{-1}$  in a 10  
26  
27 774 m long  $\times$  10 m wide  $\times$  2 m deep tank and performing an unweighted least squares adjustment  
28  
29 775 (A. Lohrmann, personal communication, 22<sup>nd</sup> October, 2015). However, it is our understanding  
30  
31 776 that this procedure is not repeated with the probes rotated  $90^\circ$ , implying that the calibration is  
32  
33 777 likely to be more robust in the longitudinal direction than in the lateral direction. Nevertheless,  
34  
35 778 Lohrmann (personal communication, 25<sup>th</sup> April, 2016) reported that the improved calibration  
36  
37 779 procedure removes curvature in velocity profiles. It is stressed that this:

- 34 780 1. is only possible if the coefficients of the transformation matrices, especially those of  
35  
36 781 beams 1 and 3, which are likely to have been most impacted by wake effects during the  
37  
38 782 calibration procedure, vary nonlinearly;
- 39 783 2. implicitly accepts that the calibration matrices vary with velocity, such that fast and  
40  
41 784 slow velocities will be biased in opposite directions (i.e. underestimates at slow  
42  
43 785 velocities and overestimates at fast velocities or overestimates at slow velocities and  
44  
45 786 underestimates at fast velocities, respectively). As of the publication date, Nortek had  
46  
47 787 commenced providing a calibration report to users detailing these biases.

48 788 At the time of writing, it has not been possible to repeat experiments 1, 2 and 3 for a  
49  
50 789 recalibrated probe. However, figure 13 compares the coefficients of the transformation matrix,  
51  
52 790  $a_{ij}$  (equation (13B)), as originally supplied and following recalibration by Nortek, for an  
53  
54 791 example probe (probe and hardware serial numbers VCN8773 and VNO1468, respectively).  
55  
56 792 The vertical variation of the calibration coefficients is compared against the theoretical values  
57  
58 793 obtained from equation (13C). The coefficients that dominate the transformation from beam  
59  
60 794 velocities to  $u$  and  $v$  deviate from the theoretical curve by a maximum of  $\pm 1\%$  until cell 27, or  
795 a range of 66 mm below the transceiver for both sets of calibration coefficients (figures 13(a))

1  
2  
3 796 and 13(b)). However, recalibration significantly reduced the cross-tristatic system coefficients  
4  
5 797 (figure 13(c)) and the coefficients that dominate the transformation from beam velocities to  $w_1$   
6  
7 798 and  $w_2$  (figure 13(d)), such that they are all much closer to their theoretical values and  $a_{32}$ ,  $a_{34}$ ,  
8  
9 799  $a_{42}$ , and  $a_{44}$  are equal to their theoretical values. Noise multipliers (not shown) are not changed  
10  
11 800 significantly.

## 12 13 801 **6.2 Parabolic noise profiles**

14  
15  
16 802 As noted, vertical profiles of the noise on the longitudinal and lateral tristatic systems,  $\sigma_{13}^2$  and  
17  
18 803  $\sigma_{24}^2$ , respectively, are parabolic with a minimum at the sweet spot (figures 8-10(b) and (d)),  
19  
20 804 where signal amplitude, SNR and  $R^2$  all reach their maxima (figures 4-6). Zedel (2008, 2015)  
21  
22 805 presented a probabilistic acoustic backscatter model and used it to quantify the form of the  
23  
24 806 intersection of the transceiver and receiver beams of a prototype bistatic system and the  
25  
26 807 Vectrino Profiler. Brand *et al* (2016) drew a schematic of the sampling volume of the Vectrino  
27  
28 808 Profiler and noted the changing area of overlap of the acoustic beams of the transceiver and  
29  
30 809 receivers. Herein, the geometry of the Vectrino Profiler, together with the assumption that all  
31  
32 810 particles that have an equal path length and lie within the intersection of the transceiver and  
33  
34 811 receiver beams are sampled simultaneously by the Vectrino Profiler, is used to estimate the  
35  
36 812 shape and size of the sampling cells of the Vectrino Profiler. This approach is less complex  
37  
38 813 than the model of Zedel (2008, 2015), but it is deterministic and permits the quantitative  
39  
40 814 description of the behaviour of the instrument.

41  
42 815 To perform these calculations, it is necessary to know the initial position, width and  
43  
44 816 spreading angle of the acoustic beams (transceiver and receivers). The outermost edge of each  
45  
46 817 receiver arm is a horizontal distance of 30.25 mm and a vertical distance of 7.9 mm from the  
47  
48 818 centre of the transceiver face (Nortek 2015b). Receivers are located on the centreline of the  
49  
50 819 receiver arm and it is assumed that the outermost edge of each receiver occurs 2 mm from the  
51  
52 820 end of the receiver arm. The initial width of the transceiver beam is defined by the diameter of  
53  
54 821 the ceramic disc transducer (6 mm, Nortek 2015b). The receiver beams are also assumed to  
55  
56 822 have an initial width of 6 mm (Nortek 2015b, Zedel 2015). For the Vectrino Profiler, the  
57  
58 823 spreading angles have not been published. Since the calibrated profiling range of the Vectrino  
59  
60 824 Profiler is 40-74 mm, this knowledge can be used to select an appropriate spreading angle for  
825 both the transceiver and the receivers, under the assumption that they are identical for all beams  
826 and the beams must intersect to yield a finite cell volume. Such a pre-calculation yields a  
827 maximum spreading angle of  $3.0^\circ$ . Support for the use of this value is given by considering the

1  
2  
3 828 transceivers of ADCP probes manufactured by Nortek, which have transceiver spreading  
4 829 angles of  $1.7^\circ$  to  $3.7^\circ$  (Nortek 2015b).

5  
6 830 Let us now consider the shape of cell volumes in the vertical plane lying through the  
7 831 transceiver and beams 1 and 3 (or, equivalently, beams 2 and 4). By definition, the sampling  
8 832 volume of a particular cell is formed by the initial  $(x, y, z)$  position of suspended particles for  
9 833 which the total distance, or time, of travel of an emitted pulse from the transceiver to the particle  
10 834 and back to a receiver is equal. The sampling volumes are therefore ellipsoidal in shape. For  
11 835 example (see figure 14), assuming 1 mm cells, cell 1 is centred 40 mm from the transceiver  
12 836 and its sampling volume is formed by the region bounded by the ellipses with tangents 39.5  
13 837 and 40.5 mm beneath the transceiver and the margins of the transceiver and receiver beams  
14 838 (figure 14). For cell 1, the relevant region is the uppermost red area in figure 14. To determine  
15 839 the extent of the next cell, all points that lie within a 1 mm longer path length are considered,  
16 840 and so on to the last cell (figure 14). The centre of mass (centroid) of each cell is demarcated  
17 841 by circles; the centroid of each cell defined by the transceiver and opposite receiver is  
18 842 demarcated by crosses (figure 14). The locations of all the cell centroids are presented in table  
19 843 2.

20  
21  
22 844 The estimated longitudinal locations of the centroids are in close correspondence with  
23 845 expectation, i.e. ranging from 40 mm to 74 mm in steps of 1 mm. Moreover, the cell centroids  
24 846 are approximately located on a straight line making a  $15^\circ$  angle with the vertical, corresponding  
25 847 to the angle of the bisector,  $\beta/2$ , that forms an approximate axis of symmetry. The cells having  
26 848 the largest measurement volumes and centroids closest to the central axis of the transceiver are  
27 849 those located between 48 mm and 50 mm from the transceiver (figure 14, table 2). These  
28 850 correspond to the sweet spot, or equivalently the intersection of the central axes of the  
29 851 transceiver and receivers. Conversely, table 2 shows that the lateral mismatch between  
30 852 receivers comprising a tristatic system exceeds the diameter of the original transmitted beam  
31 853 width in cells 21 to 35. This mismatch, together with reductions in cell volume, causes  $R^2$  and  
32 854 SNR to decrease significantly from 61 mm to 74 mm below the transceiver, even under optimal  
33 855 seeding conditions (figures 6 and 7). Reduced SNR causes increased velocity variance and  
34 856 therefore velocities sampled at cells other than the sweet spot inherently have elevated  
35 857 measurement error (*cf.* Miller and Rochwarger 1972, Zrnic 1977, McLelland and Nicholas  
36 858 2000, Zedel 2008), associated with the reduction of acoustic energy towards the edges of the  
37 859 transmitted acoustic beam. Conversely, the aspect ratio (cell width: cell height) is largest at the  
38 860 sweet spot and decreases away from the sweet spot, which causes the averaging of turbulent

1  
2  
3 861 flow structures over a considerably larger lateral distance than might be expected. The impact  
4 of this effect may be reduced somewhat by selecting larger cell heights.  
5

6 863 Comparing against the acoustic backscatter model of Zedel (2015), cell locations match  
7 well between 40 mm and 64 mm below the transceiver (+2.2 and -4.1 mm, respectively, table  
8 864 2), but diverge significantly in distal cells, where the model of Zedel (2015) predicts that SNR  
9 falls to near zero and cell locations are rather uncertain. The lateral offset of the centroids of  
10 865 the cells of paired receivers (table 2) is critical to this discussion. This offset is not accounted  
11 for when transforming beam velocities into three-component velocities, which causes an  
12 866 additional source of error. Although the resulting error introduces bias into mean three-  
13 867 component velocities (see figures 8(a) and 9(a)), it will have the greatest impact upon higher  
14 order flow statistics and is expected to be largest for flows with velocity gradients, where the  
15 868 (mean) velocity differs between the cell centres of the co-planar receivers. Furthermore, the  
16 lateral offset introduces significant complications when velocities (largely) derived from  
17 869 perpendicular beam pairs are multiplied to form covariances (e.g.  $\overline{uw}$ ,  $\overline{uw_2}$ , and  $\overline{vw_1}$ ) and  
18 variance  $\overline{w_1w_2}$  (Brand *et al* 2016) or to compute auto- or co-spectra. Brand *et al* (2016) describe  
19 870 the resulting decorrelation and underestimated (co)variance and thus recommend the use of  
20 871  $\overline{uw_1}$  and  $\overline{vw_2}$  in preference to  $\overline{uw_2}$  and  $\overline{vw_1}$ , respectively. Although  $\overline{w_1w_2}$  is affected by this  
21 872 problem, which may hinder application of the noise removal technique of Hurther and Lemmin  
22 (2001) or that derived herein, it must also be recognised that  $\overline{w_1^2}$  and  $\overline{w_2^2}$  are orders of  
23 873 magnitude noisier than  $\overline{w_1w_2}$  (table 1).  
24

25 881 In an attempt to reduce the impact of noise on the variances and covariances quantified  
26 882 by the Vectrino Profiler, in May 2016 Nortek changed their production procedure to use half-  
27 883 size receiver ceramics in the Vectrino Profiler probe, which makes the response curve “flatter”  
28 884 (i.e., the reduction of SNR through the profile is much smaller than previously: about 6 dB  
29 885 from the sweet spot to both proximal and distal cells) and makes the probe less susceptible to  
30 886 variations of the spherical scattering function of the particles that scatter sound (A. Lohrmann,  
31 887 personal communication, 25<sup>th</sup> April, 2016). It is assumed that the smaller receiver ceramics  
32 888 also have a narrower beam spreading angle, which has resulted in a shorter calibrated profiling  
33 889 range (a maximum of 40 to 70 mm). The choice to switch to smaller, more focussed receivers  
34 890 is an interesting one, and is diametrically opposed to the approach of Hurther and Lemmin  
35 891 (1998), who employ large angle receivers with their longest axis perpendicular to the receiver  
36 892 arm. At the time of writing, it has not been possible to assess whether the redesigned receivers  
37 893 yield improved data quality.  
38

## 894 7 Conclusion

895 This paper provides a comprehensive explanation of Nortek Vectrino Profiler operation and  
896 explains the behaviour, accuracy and precision of the instrument prior to the introduction of  
897 modified receiver ceramics and a modified calibration procedure in May 2016. In achieving  
898 this, it has:

- 899 1. explained the operating principles of the Vectrino Profiler and the influence of user-  
900 selectable parameters such as cell size, velocity range, and ping algorithm, on data  
901 quality;
- 902 2. employed a novel methodology to highlight the inherent bias in mean velocity estimates  
903 made with a Vectrino Profiler. Velocity magnitudes are biased by variable amounts in  
904 proximal cells, but are consistently underestimated in distal cells (figures 8-10(a)).  
905 Others (e.g., Zedel and Hay 2011, Ursic *et al* 2012, MacVicar *et al* 2014) have  
906 previously reported that overlapped profiles do not match perfectly. Since (assumed  
907 random) noise does not contribute to the mean value, noise cannot explain this bias.  
908 The extent of the bias is a function of the quality of individual probes and the calibration  
909 that transforms beam velocities to orthogonal velocities;
- 910 3. shown that when 1 mm cells are employed, amplitude (and thence signal-to-noise ratio,  
911 SNR) profiles are parabolic with a maximum at or near the “sweet spot”, 50 mm below  
912 the transceiver (figure 4). When 4 mm cells are employed, amplitude and SNR profiles  
913 decline smoothly from a broad peak between the sweet spot and the top of the profile  
914 to distal cells (figure 5);
- 915 4. investigated the influence of acoustic scatterer concentration (seeding) on amplitude  
916 and SNR (figures 4 and 5), and furthermore on correlation ( $R^2$ , figures 6 and 7), for  
917 idealised, well-distributed seeding.  $R^2$ -values increase and become more consistent as  
918 concentrations increase to an optimum level of  $\sim 3,000$  to  $6,000$   $\text{mg L}^{-1}$ , but decline at  
919 higher concentrations, especially for larger cell sizes and distal to the transceiver. This  
920 is because of signal saturation, increased scattering and attenuation. It is stressed that  
921 for the idealised conditions explored herein, seeding concentrations between  $6,000$  and  
922  $20,000$   $\text{mg L}^{-1}$  still yielded outstanding mean  $R^2$  values ( $>94\%$ ), so that concentrations  
923 in this range should not be considered overly detrimental to data quality. Sensitivity to  
924 higher seeding particle concentrations may differ for different particle types and under  
925 sub-optimal seeding conditions, e.g. in field experiments;

- 1  
2  
3 926 5. derived a new solution (equations (17)) for quantifying the noise on the two  
4 927 perpendicular tristatic systems formed by the transceiver and receivers 1 and 3 and the  
5 928 transceiver and receivers 2 and 4, respectively. This solution improves upon previous  
6 929 results (Hurther and Lemmin 2001), since it permits different estimates of noise for the  
7 930 longitudinal tristatic system,  $\sigma_{13}^2$ , and the lateral tristatic system,  $\sigma_{24}^2$ , (see figures 8-  
8 931 10(b) and (d)) which was reported by Brand *et al* (2016). Thus, it is possible to account  
9 932 for variations in the build quality of probes. In addition, the solution derived herein does  
10 933 not assume that covariances are noise free. Brand *et al* (2016) further attribute the  
11 934 difference in the noise estimates,  $\sigma_{13}^2$  and  $\sigma_{24}^2$ , to Doppler noise, which increases with  
12 935 either the cube root of the turbulence dissipation rate (Voulgaris and Trowbridge 1998)  
13 936 or the root mean square of the on-axis beam velocity (McLelland and Nicholas 2000).  
14 937 Thus, in flume experiments where flow is predominantly in the longitudinal  
15 938 (streamwise) direction,  $\sigma_{13}^2 > \sigma_{24}^2$  (figures 8-10(b) and (d)). However, in the  
16 939 experiments reported herein (figures 9 and 10(b) and (d)),  $\sigma_{13}^2$  and  $\sigma_{24}^2$  scaled with the  
17 940 (noise-free) variance of the vertical velocity (which approximates the variance of the  
18 941 on-axis beam velocity). Nevertheless, the dependence of Doppler noise on turbulence,  
19 942 as observed by many others including Hurther and Lemmin (2001) and Brand *et al*  
20 943 (2016), explains the higher noise levels at faster flow velocities (compare figures 9 and  
21 944 10(b) and (d));
- 22 945 6. confirmed that noise propagates strongly into estimates of the variances,  $\overline{u^2}$ ,  $\overline{v^2}$ ,  $\overline{w_1^2}$ ,  
23 946 and  $\overline{w_2^2}$  (see also Hurther and Lemmin 2001, Blanckaert and Lemmin 2006, Brand *et*  
24 947 *al* 2016), but weakly into the covariances  $\overline{uv}$ ,  $\overline{uw_1}$ ,  $\overline{uw_2}$ ,  $\overline{vw_1}$ , and  $\overline{vw_2}$ . Conversely,  
25 948  $\overline{w_1w_2}$  is virtually noise free, as assumed by Hurther and Lemmin (2001). Profiles of  
26 949  $\sigma_{13}^2$  and  $\sigma_{24}^2$  were shown to be parabolic, which explains the form of  $\overline{u^2}$  profiles  
27 950 observed by Zedel and Hay (2011) and provides an explanation for the apparent error  
28 951 in profiles of  $\overline{u^2}^{1/2}$  reported by MacVicar *et al* (2014). Although Brand *et al* (2016)  
29 952 showed that the method of Hurther and Lemmin (2001) can remove a large fraction of  
30 953 the noise included in the variances, the solution for estimating noise derived herein may  
31 954 also be used to remove noise from the variances and covariances (table 1). This  
32 955 conclusion may be validated through direct comparison against independent  
33 956 measurements undertaken with an alternative method (e.g., as performed with LDV for  
34 957 a non-profiling ADV, Voulgaris and Trowbridge 1998);

- 1  
2  
3 958 7. explained how the probe geometry causes the four receivers to intersect at a single  
4 959 location in the vertical (the sweet spot), where the sampling volume is largest, but that  
5 960 the geometry of the receivers causes spatial divergence of the sampled position both  
6 961 proximal and distal to the transceiver (figure 13). This spatial divergence yields a  
7 962 significant reduction in the size of the sampled area and a decrease in SNR, resulting in  
8 963 reduced data quality proximal and distal to the transceiver. This, combined with  
9 964 consideration of the form of  $R^2$  profiles, suggests that reliable velocity data are most  
10 965 likely to be collected in the region between 43 and 61 mm below the transceiver;  
11 966  
12 967 8. highlighted the fact that the bias inherent in estimates of the second order flow statistics  
13 968 may be reduced but cannot be removed with sensor improvements, since Doppler noise  
14 969 is to a large extent a function of the flow field. A revised calibration procedure may  
15 reduce bias in mean velocity estimates but it is unlikely to entirely remove it.

## 970 **Declaration of interest**

971 We wish to confirm that there are no known conflicts of interest associated with this publication  
972 and there has been no significant financial or in-kind support for this work that could have  
973 influenced its outcome.

## 974 **Acknowledgements**

975 We wish to thank Dr. Chris Unsworth for undertaking the tests described and reported in  
976 sections 4.1 and 6.1 while he undertook PhD studies at the University of Hull. We are also  
977 grateful to the technical staff of the Hydraulics Laboratory at Ghent University for constructing  
978 the experimental setup described in sections 4.2 and 6.2. In addition, we wish to acknowledge  
979 Atle Lohrmann of Nortek AS and Robert Craig of Nortek Scientific, who have accommodated  
980 myriad requests for information about the Vectrino Profiler. RET wishes to thank the Institute  
981 of Applied Geosciences at the School of Earth and Environment at the University of Leeds for  
982 financial assistance that enabled attendance of the Nortek European User Symposium that was  
983 held in Karlsruhe, Germany, in October 2015, LS is grateful to the Research Foundation -  
984 Flanders for funding his Ph.D. fellowship, while SC is grateful to the Special Research Fund  
985 (BOF) of Ghent University for funding his Ph.D. fellowship. The tests described and reported  
986 in sections 4.3 and 6.3 were supported in part by the European Community's 7<sup>th</sup> Framework  
987 Programme through a grant to the budget of the Integrated Infrastructure Initiative  
988 HYDRALAB IV, Contract no. 261520.

3 1039 **Nomenclature**  
4  
5

- 6 1040  $\beta$  bisector of the angle between paths of the transmitted and received pulses  
7  
8 1041  $\gamma$  random angle  
9  
10 1042  $\delta$  angle  $V$  makes with  $\beta$   
11  
12 1043  $\varepsilon$  relative root mean square error  
13  
14 1044  $\Delta\phi$  phase shift  
15  
16 1045  $\sigma^2$  noise if all receivers have equal noise  
17  
18 1046  $\sigma_{13}^2, \sigma_{24}^2$  noise on longitudinal and lateral tristatic systems, respectively  
19  
20 1047  $\tau$  integral time scale  
21  
22 1048  $a$  coefficient of the transformation matrix to transform between beam and Cartesian velocities  
23  
24 1049  $c$  speed of sound within the water ( $\approx 1480 \text{ m s}^{-1}$ , dependent on temperature and salinity)  
25  
26 1050  $d_1, d_2$  diameters of the transmitted beam at the top and bottom of a cell  
27  
28 1051  $D_{15}, D_{85}$  particle diameters for which 15% and 85% of the distribution are finer  
29  
30 1052  $f$  frequency of sound emitted by the transceiver (10 MHz)  
31  
32 1053  $f_s$  sampling frequency  
33  
34 1054  $i$  cell number  
35  
36 1055  $j, k, l, p$  indices  
37  
38 1056  $L$  cell size (= cell height)  
39  
40 1057  $n$  unbiased noise on  $V_b$   
41  
42 1058  $N$  amplitude of incoherent backscatter  
43  
44 1059  $NPP$  number of pulse-pairs averaged by the Vetrino Profiler  
45  
46 1060  $\Delta R_R, \Delta R_T$  distance between a scatterer and a receiver and the transceiver, respectively  
47  
48 1061  $\Delta R$  total travel distance of a pulse ( $= \Delta R_T + \Delta R_R$ )  
49  
50 1062  $\Delta t$  ping interval or time delay  
51  
52 1063  $\Delta t_D$  dwell time introduced when transmit pulses longer than 1 mm are combined with  $\Delta t < 175$   
53

## Figures

**Figure 1.** (a) Illustration of the operation principle of the Vectrino Profiler profiling ADV, showing the cause of the phase difference detected between the emission of Pulses 1 and 2. Note that the geometry of the acoustic pulse paths is exaggerated to aid visualisation; (b) Definition of the parameters of equations (4) and (5), where  $R_T$  is the distance between a scatterer and the transceiver,  $R_R$  is the distance between a scatterer and a receiver,  $\mathbf{V}$  is the velocity vector of a scatterer, which makes a random angle  $\delta$  with the bisector of the angle  $\beta$  between the paths of the transmitted and received pulses. The red collar signifies the receiver arm that points in the positive  $x$ -direction.

**Figure 2.** Schematic illustration of the signal strength received by the receivers of a Vectrino Profiler profiling ADV and range gating. The horizontal axis denotes time, but has been written as distance from the central transceiver.

**Figure 3.** a) Schematic illustration of the location of the sampling volumes of the Vectrino Profiler (not to scale). The red collar signifies the receiver arm that points in the positive  $x$ -direction. Note that the Vectrino Profiler has a right-handed coordinate system. b) The methodology used in Experiment 2: after a measurement, the Vectrino Profiler was moved vertically by one 2 mm cell height, so that in the subsequent measurement, the same physical location was located in the neighbouring cell above. A similar methodology was adopted in Experiment 3, except that the Vectrino Profiler was moved vertically by an increment of four 1 mm cell heights.

**Figure 4.** Range below transmitter against mean amplitude for 1 mm cells for an example Vectrino Profiler (Experiment 1).

**Figure 5.** Range below transmitter against mean amplitude for 4 mm cells for an example Vectrino Profiler (Experiment 1).

**Figure 6.** Range below transmitter against mean correlation for 1 mm cells for an example Vectrino Profiler (Experiment 1).

**Figure 7.** Range below transmitter against mean correlation for 4 mm cells for an example Vectrino Profiler (Experiment 1).

**Figure 8.** Variation of parameters at a height of 30 mm above the bed, quantified by raising the Vectrino Profiler in increments of one cell height (cell height = 2 mm) between each 120 s sampling period (Experiment 2). Cell number 6 contains the sweet spot. All Kaolin series were measured with the high power setting. (a) mean longitudinal velocity (error bars represent 95% confidence intervals); (b) Noise on receivers 1 and 3; (c) mean SNR in the plane of receivers 1 and 3; and (d) Noise on receivers 2 and 4. Note that results obtained when the probe was oriented at  $90^\circ$  and  $180^\circ$  have been transformed so that they have the same direction as the measurement undertaken at an orientation of  $0^\circ$ . Thus, the longitudinal tristatic system at an orientation of  $90^\circ$  is the lateral tristatic system at an orientation of  $0^\circ$  and the lateral tristatic system at an orientation of  $90^\circ$  is the longitudinal tristatic system at an orientation of  $0^\circ$ .

**Figure 9.** Variation of parameters at a height of 30 mm above the bed, quantified by raising the Vectrino Profiler in increments of four cell heights (cell height = 1 mm) between each 240 s sampling period (Experiment 3). The sweet spot occurs between positions 3 and 4. Black lines and circles: pump frequency 10 Hz, ambiguity velocity  $0.085 \text{ m s}^{-1}$ ; mid-grey lines and triangles: pump frequency 10 Hz, ambiguity velocity  $0.185 \text{ m s}^{-1}$ ; light-grey lines and diamonds: pump frequency 10 Hz, ambiguity velocity  $0.343 \text{ m s}^{-1}$ . (a) mean longitudinal velocity (error bars represent 95% confidence intervals); (b) Noise on receivers 1 and 3 normalised by the (virtually noise free) vertical normal stress; (c) mean SNR in the plane of receivers 1 and 3; and (d) Noise on receivers 2 and 4 normalised by the (virtually noise free) vertical normal stress.

**Figure 10.** Variation of parameters at a height of 30 mm above the bed, quantified by raising the Vectrino Profiler in increments of four cell heights (cell height = 1 mm) between each 240 s sampling period (Experiment 3). The sweet spot occurs between positions 3 and 4. Black lines and circles: pump frequency 25 Hz, ambiguity velocity  $0.185 \text{ m s}^{-1}$ ; grey lines and triangles: pump frequency 25 Hz, ambiguity velocity  $0.343 \text{ m s}^{-1}$ . (a) mean longitudinal velocity (error bars represent 95% confidence intervals); (b) Noise on receivers 1 and 3 normalised

1  
2  
3 by the (virtually noise free) vertical normal stress; (c) mean SNR in the plane of receivers 1 and 3; and (d) Noise  
4 on receivers 2 and 4 normalised by the (virtually noise free) vertical normal stress.  
5

6 **Figure 11.** Variation of mean beam velocities (error bars represent 95% confidence intervals) at a height of 30  
7 mm above the bed, quantified by raising the Vectrino Profiler in increments of four cell heights (cell height = 1  
8 mm) between each 240 s sampling period (Experiment 3). The sweet spot occurs between positions 3 and 4. (a)  
9 pump frequency 10 Hz, (b) pump frequency 25 Hz. Black lines: ambiguity velocity  $0.085 \text{ m s}^{-1}$ ; blue lines:  
10 ambiguity velocity  $0.185 \text{ m s}^{-1}$ ; red lines: ambiguity velocity  $0.343 \text{ m s}^{-1}$ .  
11

12 **Figure 12.** Variation of noise parameters at a height of 30 mm above the bed, quantified by raising the Vectrino  
13 Profiler in increments of one cell height (cell height = 2 mm) between each 120 s sampling period (Experiment  
14 2, clear water, high power series). Cell number 6 contains the sweet spot. (a) noise according to the correction  
15 method of Hurther and Lemmin (2001) and the correction method presented herein; (b) percentage difference  
16 between vertical velocity variances; (c) longitudinal velocity variance; and (d) lateral velocity variance.  
17

18 **Figure 13.** Comparison of theoretical (equation 13C) and empirical transformation matrix coefficients,  $a_{ij}$   
19 (equation 13B), of the Vectrino Profiler with probe and hardware serial numbers VCN8773 and VNO1468,  
20 respectively, prior to and after recalibration by Nortek. (a) positive coefficients that dominate the transformation  
21 from beam velocities to  $u$  and  $v$ ,  $a_{11}$  and  $a_{22}$ , respectively; (b) negative coefficients that dominate the  
22 transformation from beam velocities to  $u$  and  $v$ ,  $a_{13}$  and  $a_{24}$ , respectively; (c) cross-tristatic system coefficients;  
23 (d) coefficients that dominate the transformation from beam velocities to  $w_1$  and  $w_2$ ,  $a_{31}$  and  $a_{33}$ , and  $a_{42}$  and  $a_{44}$ ,  
24 respectively.  
25

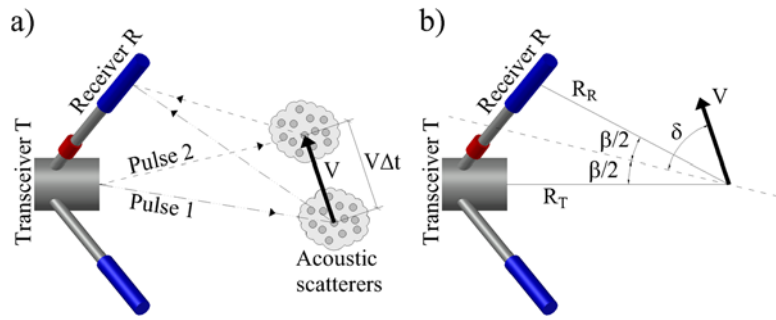

26 **Figure 14.** Estimated measurement volumes (colour bands) of the Vectrino Profiler for a cell height of 2 mm.  
27 The acoustic beams are also drawn, showing the assumed width and spreading angle of the beams. Open circles  
28 present the centres of the measurement volumes, while the crosses present those of the other receiver located in  
29 the same plane.

**Table 2.** Estimated location of the centres of the measurement volumes and the lateral mismatch between the two receivers located in the same plane.

Cell number	Vertical distance (mm)	Lateral distance (mm)	Lateral mismatch between two co-planar receivers (mm)
1	40.1	2.2	4.4
2	41.1	1.9	3.8
3	42.1	1.6	3.3
4	43.1	1.4	2.7
5	44.1	1.1	2.2
6	45.1	0.8	1.7
7	46.1	0.6	1.1
8	47.1	0.3	0.6
9	48.1	0.1	0.2
10	49.1	-0.1	-0.1
11	50.1	-0.3	-0.7
12	51.1	-0.6	-1.2
13	52.1	-0.9	-1.7
14	53.1	-1.1	-2.3
15	54.1	-1.4	-2.8
16	55.1	-1.7	-3.3
17	56.1	-1.9	-3.9
18	57.1	-2.2	-4.4
19	58.1	-2.5	-4.9
20	59.1	-2.7	-5.5
21	60.1	-3.0	-6.0
22	61.1	-3.3	-6.5
23	62.1	-3.5	-7.1
24	63.1	-3.8	-7.6
25	64.1	-4.1	-8.2
26	65.1	-4.3	-8.7
27	66.1	-4.6	-9.2
28	67.1	-4.9	-9.7
29	68.1	-5.1	-10.3
30	69.1	-5.4	-10.8
31	70.1	-5.7	-11.3
32	71.1	-5.9	-11.9
33	72.0	-6.2	-12.4
34	73.0	-6.5	-12.9
35	73.9	-6.7	-13.4
