Abstract: The fixed bed gasification of lignin rich and deficient mixtures was carried out to probe the synergistic effects between two model compounds, Lignin Pink (LP) rich in Na and Cellulose Microcrystalline (CM). Reaction conditions utilized the most commonly used air ratios in current wood gasifiers at 750 °C and 850 °C. It was found that by increasing the lignin content in the mixture, there was a selectivity change from solid to gas products, contrary to a similar study previously carried out for pyrolysis. This change in product mix was promoted by the catalytic effect of Na edge recession deposits on the surface of the char. As a result, the water gas shift reaction was enhanced at 850 °C for the LPsCMs mixture across all air ratios, this was evidenced by a strong correlation between the produced H2 and CO2. Meanwhile, by lowering the lignin content in the mixtures, the reactivity of cellulose microcrystalline was found to generate more char at higher temperature, similar to lignin mixtures when undergoing pyrolysis.

1. Introduction

The utilization of sustainable solid fuels such as woody wastes is one of many possible answers to combat irreversible climate change damage, attributed to the extensive usage of fossil-based fuels such as coal and the corresponding CO2 emissions produced [1]. One method of replacing the polluting coal, rich in mineral ash constituents, is the use of biorenewable feedstocks, specifically lignocellulosic biomass wastes where upon the carbon cycle can be closed. This can be also done by co-processing, or diluting the coal feed with other wastes such as pulps, pyrolysis tars or lignin rich biorefinery sludges and even other biodegradable by-products. Here, the overall net CO2 emissions can be reduced to zero as a part of the natural carbon cycle, or even to negative if used in conjunction with modern carbon capture technologies [2]. Currently, a popular feedstock used on a large scale for bioenergy production are woody biomass residues, these are physically, chemically or physicochemically pretreated [3,4] and fed into thermochemical reactors for pyrolysis (mainly solid to liquid thermal cracking reactions) [5-7], gasification or combustion (mainly solid to gas, gas-gas and thermochemical cracking reactions) [8,9]. However, variability of the lignocellulosic biomass waste is a limiting factor in the use of large-scale waste reformation for the production of low carbon energy [10]. This is due to wide variations in cellulose, hemicellulose and lignin ratios depending on the feedstock (woody vs herbaceous). As a result, the chemical interactions and bonding brings in a new paradigm as the feedstocks will each have differences in the required energy to thermally...
decompose. Additionally, the presence and role of any inorganic ash constituents that may be present in the substrate such as Na, K, S, Ca, Si, Mg or Cl must be considered. These elements form compounds which can cause extensive damage to reactor systems, promote side reactions which cause fouling, slagging and de-fluidization. Ultimately this leads to a breakdown in combustible fuel gas production [11,12]. Additionally, inorganic components can catalyze the production of specific gas products or produce toxic emissions in their own right such as H₂S or HCl [13,14].

Previously in 2018, work was published by Volpe, Zabaniotou and Skouloiu whom found that there is a synergistic effect between lignin and cellulose model compounds during pyrolysis [15]. It was found that by varying the ratios between Lignin Pink and Cellulose Microcrystalline (Figure 1), the thermochemical process outcome is altered. This is where increased lignin content alters the reaction selectivity to generate more char. However, when compared to a ‘real’ feedstock such as olive kernels or corn cobs the product mixtures are not the same. This is due to the feedstock variability as mentioned previously which operates a wide range of thermochemical and tar thermal cracking reactions that promote a different process due to an ‘additive rule’. As a continuation of this work, the model compounds underwent gasification across various temperatures and air ratio (ϕ) values, where air ratio represents the ratio of the gasification air content to the total stoichiometric air required for complete oxidation of a specific fuel. In line with our previously published work [15], an assumption was made that various agro-residues of interest could be fairly resembled with synthetic mixtures, composed only from cellulose and lignin. This is due to the relatively low hemicellulose content which exists in both woody and herbaceous lignocellulosic waste. It was assumed that the hemicellulose component would contribute a minor role during gasification due to its similarities to cellulose [16].

This work demonstrates the effect of lignin and cellulose model compound wt% ratios on the ratios of fuel gas species generated under varying gasification conditions, as well as the liquid and solid products. The selected gasification conditions are the ones most commonly used in autothermal industrial-scale woody biomass waste gasifiers [17]. Previously, for the pyrolysis of model compound mixtures, it was found that the char yield was enhanced for lignin rich mixtures across all temperatures, an inverse trend was shown for tar where cellulose rich mixtures were found to produce a higher tar selectivity [15]. Figure 1 as well as the ultimate analysis shown in our previous work [15] show that the lignin model compound, Lignin Pink (LP), contains both Na and S, 8.7 wt% and 12.6 wt%, respectively. However, this is contributing to less than <0.1 wt% ash content for the lignin model compound [15]. The ash values observed for pure lignocellulosic biomass feedstocks are very much higher, ranging in some cases >5 wt% [3]. Alternative waste feedstocks with higher inorganic content are black liquor and pyrolysis oils as well as sludges produced during fossil fired conventional energy generation [18]. It has previously been found that lignin thermochemical decomposition, specifically char degradation can be promoted by Na [19]. This has been also shown for the LP compound previously [20]. High Na content in a model compound is comparable to real world feedstocks such as olive cake [21], olive wood [22], poplar bark [22] and fir mill residues [22]. It also exists in high concentrations in wheat straw [23] and buffalo gourd grass [22]. This behavior means that Na present will force charring reactions leading to an increase in gaseous products [20].

As the temperature of gasification increases from 800 °C the rate of Na released into the gas phase increases in a non-linear fashion. This is because Na released to the gas phase at lower temperatures is transferred to the produced char forming channels in the carbon interface during gasification [24], often forming larger mesopores than other alkali metals. This makes sodium, much like potassium and calcium, edge-recession catalysts [24,25]. It has been shown in the past that the presence of Na can effectively catalyze the water-gas shift reaction (CO + H₂O → CO₂ + H₂), a mildly exothermic reaction, boosting the production of CO₂ and H₂ [24]. Although seen as less active than K for gasification, the Na present from the LP should provide a promotional effect on the gasification. The presence of residual ash is appropriate for this model reaction as pretreatments for most lignocellulosic waste feedstocks are not suitable at extracting all inorganics [3,11,12,26].
2. Materials and Methods

2.1 Sample Preparation and Characterization

Cellulose Microcrystalline (CM) and Lignin Pink (LP) were supplied by Sigma-Aldrich GmbH and Alfa Aesar U.S.A., respectively. In the same method mentioned previously [15], the LP and CM model compounds were thoroughly mixed in weight percentages of 17 wt% LP, 83 wt% CM (LP:CM50) to generate a lignin deficient material and 48 wt% LP, 52 wt% CM (LP:CM50) to resemble a material with a higher lignin content to mirror the composition of herbaceous and woody ‘real’ feedstocks such as alfalfa, pine straw and flax fiber [27]. Individual proximate and ultimate analysis of the model compounds is presented in earlier work, where data was obtained from the supplier directly [15].

2.2 Gasification Experimental Study

Similarly, to the experimental setup described in more detail previously [15], the gasification of CM and LP (particles sizes dₚ = 100-200 μm) was carried out in a lab scale, downdraft fixed bed stainless steel batch atmospheric reactor under a controlled reactive atmosphere. Here, synthetic air (O₂: 20% and N₂: 80%) was diluted by a mass flow controller with nitrogen, to achieve the most commonly practiced gasification air ratios (λ) of 0.2, 0.3 and 0.4, to a flow rate of 20 mL/min, corresponding to ~0.4 s of gas residence time. The gasifier was heated to 750 °C and 850 °C, measured by a K-type thermocouple positioned in the sample holder of the reactor, the heating rate was calculated to be approximately 150 °C/min for a total reaction time of 20 min. Producer gas cleaning and subsequent sampling were carried out downstream from the reactor. Upon full gasification of the model compounds the reactor was cooled and disassembled to reclaim the char residue. The total tar yield including the aqueous phase was determined by subtraction of the produced gaseous and char products as illustrated by the overall general mass balance in equation 1.

Eq 1 - Carbonaceous feedstock + Gasification medium (air) = Char + Gasification producer gas + Tar

The most common gas phase products were sampled via airtight gas sampling bags and analysed offline on an Agilent 6890N chromatograph fitted with two columns, HP-PlotQ and HP-Molsieve, with both an FID and TCD detectors. More details on the specific experimental systems can be found in previous published works by the authors [12,15,28].

3. Product Analysis and Discussion

Figure 2a, b, c and d show the product mix generated from the gasification with air of each of the model compound mixtures at two different temperatures (750 °C and 850 °C) and three different reaction atmospheres (λ = 0.2, 0.3, 0.4), corresponding to different under-stoichiometric air ratios and starting from the pure lignin (LP100) in Figure 2a and decreasing, to a rich in lignin mixture, diluted with cellulose LP:CM50 (Figure 2b), a low lignin mixture LP:CM50 (Figure 2c) and the pure cellulose.
CM100 (Figure 2d). In our previous pyrolysis study, we found that the char yields were enhanced when using lignin rich mixtures [15]. However, in all cases (temperature and air ratio) for gasification this trend was not seen. In fact, the LP alone facilitated a far greater tar yield (Figure 2a) where it was found ~25-30 wt% of the product mix was tar based at \( \lambda = 0.2 \) and 0.3 conditions, corresponding to the high temperature pyrolytic stage of gasification. This might be attributed to the role of Na cations liberated during the thermal decomposition of the LP. Not only is the lignin decomposition pathway enhanced by Na, dehydration, demethoxylation (-OCH\(_3\)), decarboxylation (-COOH) reactions as well as char formation have been found previously to be catalyzed [29]. Although found to enhance various reactions, Na has been found to decrease the yield of organic volatiles and CO [29]. This has been echoed by Huang et al. who show that the reactivity of lignocellulosic chars increase with the addition/presence of metals, the order of promotion decreases down the following series, K > Na > Ca > Fe > Mg [30]. The major product intended from gasification are fuel gases, Figure 2b shows that by using the lignin rich LP\(_{48}\)CM\(_{52}\)mixture at 850 °C there is a substantial selectivity change from char to gas, this is where over 64 wt% of the product mix was gas for an air ratio of \( \lambda = 0.4 \). Whereas for the same mixture at 750 °C under the same \( \lambda \) value there was only 25 wt% gas produced overall. It is clear from Figure 2a that overall, LP is responsible for low gas yields, as compared with mixtures and pure CM, Figure 2d, at 750 °C. By considering the gasification of the pure cellulose (CM100) (Figure 2d) there was a maximum of 22.7 wt% gas produced. Although for the CM a maximum char yield, 74 wt%, could be obtained by using \( \lambda = 0.3 \) at 750 °C. With the exception of the pure lignin sample (LP\(_{100}\)), a maximum tar yield was generated for all mixtures in the lowest air ratio conditions (\( \lambda = 0.2 \)), as was expected. It is clear that the gasification at conditions of higher \( \lambda \) ratio in the reactor promote char decomposition rather than restricting formation, especially at 850 °C (Figures 2b and 2c).

---

Figure 2 – Product distribution of; (a) LP\(_{100}\), (b) LP\(_{48}\)CM\(_{52}\), (c) LP\(_{17}\)CM\(_{83}\) and (d) CM\(_{100}\) at two different gasification temperature parameters, 750 °C and 850 °C. Air content in the flux is indicated by \( \lambda \).
To determine the effect of reactant synergies, the gas product (normalized, excluding N2) selectivities have been presented in Figures 3a-3d, where Figure 3a is the undiluted LP\textsubscript{100} at 750 °C, while in Figure 3b is LP\textsubscript{α}CM\textsubscript{52}, Figure 3c is LP\textsubscript{β}CM\textsubscript{60} and Figure 3d is the undiluted CM\textsubscript{100} sample, at both operational temperatures. For the low temperature gasification (750 °C) of LP under λ = 0.2, far more H\textsubscript{2} and CO are formed as compared with the higher air ratio (λ = 0.4). This is where a decrease of 41% and 30% was observed for H\textsubscript{2} and CO, respectively. As the O\textsubscript{2} concentration was increased in the stream, the fuel gas selectivity drops significantly, favored by the richer oxygen atmosphere and residual Na in the form of Na\textsubscript{2}CO\textsubscript{3} decomposing to form CO\textsubscript{2}. By diluting the lignin content within the mixture, Figure 3b shows that the production of both CO and H\textsubscript{2} have been increased dramatically at 850 °C. This data also shows that by increasing the air content, there is an increase in the selectivity of CO opposed to CO\textsubscript{2}, shown in Figure 3a. By mixing the two compounds together there has been a profound decrease in CH\textsubscript{4} production (Figure 3b and Figure 3c) at both temperatures, as compared with LP\textsubscript{100} (750 °C, λ = 0.2) and CM\textsubscript{100} (850 °C, λ = 0.2). For the low temperature gasification of LP\textsubscript{α}CM\textsubscript{52} (Figure 3c) there has been a large switch in selectivity towards CO\textsubscript{2} across all λ values. At its maximum (λ = 0.3), 52% of the product mix was CO\textsubscript{2} for the same reaction conditions this was 14.3% and 26.1% higher for LP\textsubscript{100} and LP\textsubscript{α}CM\textsubscript{52}, respectively. However, the lower lignin containing mixture (Figure 3e) produces far less CO than LP\textsubscript{α}CM\textsubscript{52} shown in Figure 3b. This mixture shows a true synergistic effect between both compounds as the H\textsubscript{2} and CO production is far higher than LP\textsubscript{100} (Figure 3a) and CM\textsubscript{100} (Figure 3d) alone. Figure 3d does report the highest selectivities towards ethylene (C\textsubscript{2}H\textsubscript{4}) and ethane (C\textsubscript{2}H\textsubscript{6}), 0.8% and 1.0% when operating at 850 °C and λ = 0.2. As the oxygen is increased in the stream the selectivities of these two molecules drops to 0.5% and 0.1%, respectively. Interestingly this drop is only observed for LP\textsubscript{α}CM\textsubscript{52} (Figure 3b) where there is no production of ethylene or ethane. CM\textsubscript{100} when gasifying at 750 °C and λ = 0.4 was found to possess more combustion characteristics, producing 50.4% of CO\textsubscript{2} (Figure 3d). Although higher than LP\textsubscript{100} under the same conditions, both mixed materials were found to produce less CO\textsubscript{2} across both temperatures, at λ = 0.4. Overall, from Figure 3 two general conclusions can be made: a) the increase of gasification temperature leads to an increase in H\textsubscript{2} content in the producer gas. This is due to the water-gas shift reaction and the hydrogen enriched gas mechanisms being temperature dependent and commonly promoted at the industrial scale by alkali and alkaline-earth metal catalysts, such as Na [31]. Also, hydrogen is liberated due to heavy volatiles cracking on the char matrix [15,28]. Additionally, b) the effect of air ratio on the produced gasses is not directly connected with the reduction of H\textsubscript{2} concentration, and/or the increase of CO\textsubscript{2}. 
Figure 3 – Gas phase product composition of; (a) LP<sub>100</sub>, (b) LP<sub>48</sub>CM<sub>52</sub>, (c) LP<sub>17</sub>CM<sub>83</sub> and (d) CM<sub>100</sub> at two different gasification temperature parameters, 750 °C and 850 °C. Air content in the flux is indicated by λ.

Figure 4a and 4b illustrates the correlation between the H<sub>2</sub> content and the CO<sub>x</sub> in the producer gas at 750 °C and 850 °C, respectively. It is worth noting that in both figures a strong linear correlation between H<sub>2</sub> and CO, CO<sub>x</sub> is noticed. More specifically the increase of carbon oxides (CO<sub>x</sub>) in the producer gas decreases the production of H<sub>2</sub> and vice versa. Figure 4a shows that for LP<sub>17</sub>CM<sub>83</sub> there is a greater concentration of CO<sub>x</sub> molecules at 750 °C, across all air ratios (dark blue square). This is due to the greater char yields receiving a solid-gas reaction promotion from isolated Na deposits, donated by the LP. However, when operating at 850 °C there is not the same promotional effect observed for LP<sub>17</sub>CM<sub>83</sub> but for the lignin rich mixture (LP<sub>48</sub>CM<sub>52</sub>) there is a substantial decrease in char yield. It is suspected that the Na rich deposits have enhanced the water-gas shift reaction, thermochemically decomposing the char with reactively formed steam. Figure 4b shows that this effect is shown across all three reactions, this means that the O<sub>2</sub> content is not important as an equilibrium has been reached (red square). The greater Na effect is assumed to be attributed to the decomposition of char (Figure 2b). As char is decreased, the CO evolved is readily reacted with produced steam in the reaction.
Figure 4 – Correlation between hydrogen and carbon oxides at two different gasification temperatures, a) 750 °C (dark blue square indicating LP:CMs) and b) 850 °C (red square indicating LP:CMs). For all experimental mixtures and conditions.

4. Conclusions

The gasification of the model compound mixtures containing Lignin Pink and Cellulose Microcrystalline took place under the most common varying oxygen containing atmospheres (λ = 0.2, 0.3, 0.4) and temperatures (750-850 °C) for current wood gasifiers. Here, varying ratios of the two compounds were used to examine the synergistic behavior between lignin and cellulose. An opposite trend was found to what was observed previously in our pyrolysis study, that char yields were enhanced when using lignin rich mixtures. For gasification it was found that CM rich mixtures produced more char, while lignin rich compounds produced a greater gas yield at 850 °C. It is believed that due to the catalytic activity of Na in gasification, specifically at higher air content. As the Na forms channels decorating the surface of the formed char, gas phase reactions are promoted, specifically through the water-gas shift reaction, where reactively formed steam interacts with the char. It was found that the lignin rich LP:CMs mixture when operating at 850 °C provided the highest producer gas product mix. By increasing the Cellulose Microcrystalline content in the mixture, the oxidization process was accelerated where CO₂ was found to be the dominant product. In addition, a strong correlation between the produced H₂ and COₓ is observed. It was found that the Lignin Pink rich mixture received a substantial promotional effect from Na deposits decorating the surface of the char, enhancing the water-gas shift reaction and hydrogen enrichment mechanism when operating at 850 °C. As a result, the product mix was heavily pushed toward gas phase products opposed to charring reactions at 750 °C. The significance of the presented results enhance the existing literature with a series of experimental results useful for simulation, modelling and validation studies for the pyrolysis and or gasification of new era wastes. Examples of such are, feedstocks naturally high in Na, sludges from NaOH delignification processes and alkaline metal ion containing wastes from biorefineries.
